In lanthanide atoms, the configuration of the valence electrons of the outermost shell is the same for all the species while the 4f orbitals are progressively filled with the increase in atomic number, while the 5s and 5p subshells are already filled and screen the 4f orbitals; this makes the physical and chemical properties of these elements remarkably similar. Another consequence is the so-called 'lanthanide contraction' in which the ionic radius decreases progressively from La³⁺ to Lu³⁺ as inefficient shielding of the increased nuclear charge by the extra 4f electrons causes the 5s and 5p electrons to contract in toward the nucleus. The progressive decrease of the ionic dimension changes the charge/radius ratio influencing their reactivity, especially in aqueous solutions. In natural environments, most lanthanides occur as trivalent ions except for Ce (cerium) that may also be +4 in oxic conditions (>300 mV at pH 7). Samarium (Sm), europium (Eu) and ytterbium (Yb) may reach the +2 state under extremely low

Lanthanides, although they belong to the ‘rare’ elements group, are not actually rare on Earth. Their estimated average concentration in the Earth’s crust ranges from around 130 mg kg⁻¹ to 240 mg kg⁻¹, which is greater than other commonly exploited elements. Cerium is more abundant in the Earth’s crust than copper (Cu); neodymium (Nd) and La are more abundant than lead (Pb), and praseodymium (Pr), Sm and gadolinium (Gd) are more abundant than tin (Sn). [Table 1](#) presents the average abundances (in mg kg⁻¹) of lanthanides in Earth’s crust ([from Wedepohl, 1995](#)). Although not rare, they are seldom concentrated into economically-significant amounts for extraction. Despite this fact, there were only 184,000 t of all 17 Rare Earth Oxides produced globally in 2018 compared with 21 million t of copper, 4.4 million t of lead and 310,000 t of tin in the same year ([Castilloux, 2019](#)).

Lanthanides are non-essential elements for life but, due to their unique physical and chemical properties, they have become extremely important as a component of present-day life because of their widespread application in a variety of technologies. These elements have distinctive magnetic, phosphorescent, and catalytic properties (e.g., Ce, La, Nd, and Gd). Lanthanides are used in

Fig. 2 Estimated global demand for Nd, Pr, Dy, and Tb for wind turbine generators, motors for electric vehicles and other sectors, according to low- and high-demand scenarios. From: Alves Dias P, Bobba S, Carrara S, Plazzotta B (2020) The role of rare earth elements in wind energy and electric mobility, EUR 30488 EN. Luxembourg: Publication Office of the European Union, ISBN 978-92-79-27016-4, doi:10.2760/303258, JRC122671.

many domestic, medical, industrial, and strategic applications because of their unique catalytic, metallurgical, nuclear, electrical, magnetic, and luminescent properties. Examples of the many applications for REE are their use in magnets and super magnets, electric motors, metal alloys, electronic, and computing equipment, batteries, catalytic converters, petroleum refining, medical imaging, coloring agents in glass and ceramics, phosphors, lasers, and glass. A stable provision of lanthanides for the next 20–30 years is therefore important for the success of transitioning into a carbon-neutral society (Fig. 2).

The elements of the lanthanide group (and rare earth elements in general) have recently become ‘contaminants of emerging concern’ (CEC). The concern arises because (i) they are currently unregulated, (ii) they are not routinely monitored in environmental and public health programs, (iii) they are micropollutants detectable with analytical equipment with very low detection limits, and (iv) their mechanisms of environmental and human toxicity are poorly understood.

The concentration of lanthanides in the soil is very variable, with a mean concentration of REE in the topsoil of Europe of 125.6 mg kg^{-1} , which is close to that of the upper continental crust (146.4 mg kg^{-1}) (Gwenzi et al., 2018). However, typical contents vary from a few tens of mg kg^{-1} for Nd to a few hundreds of mg kg^{-1} for the sum of the rare earth elements, of which lanthanides are a large part (Laveuf and Cornu, 2009). This large variation depends mainly on the type of parent material from which the soil originated. In some tropical soils of Brazil, Silva et al. (2020) found that the background concentrations of lanthanides and their spatial variation were dependent on the concentration of iron (Fe) oxides. In Germany, on the contrary, Mihajlovic and Rinklebe (2018) found that the dependence of lanthanide content on the soil parent material decreased in the order: carbonatite > basalt > orthogneiss > clay slate > loess > sandstone > Pleistocene and Holocene sediments > organic material.

The majority of all mineral resources that contain lanthanide are concentrated in the minerals bastnasite, monazite, and xenotime. Other minerals, typically heavy minerals such as anatase, ilmenite, sphene, rutile, and zircon, can also contain lanthanides. These minerals are relatively resistant to weathering; therefore, they do not contribute significantly to the mobility of the lanthanides. Phosphatic minerals can contain large REE concentrations—in the order of thousands of mg kg^{-1} of lanthanides—depending on the origin and genesis of the phosphate. Apatite is the main mineral used for the production of phosphate fertilizers, and lanthanide in apatite comes from the substitution of Ca by ions of trivalent lanthanide. The P-fertilizers are thus an indirect but relevant anthropogenic source of lanthanides in soils. It has been calculated that with a P-fertilizer application of $300 \text{ kg ha}^{-1} \text{ year}^{-1}$, the input of lanthanides can range from 30 to $170 \text{ g ha}^{-1} \text{ year}^{-1}$ (Laveuf and Cornu, 2009). In addition to this indirect input, in recent years lanthanides have been used as a complement to fertilizers to increase seed germination, root growth, chlorophyll content, plant resistance, and agricultural productivity (Gwenzi et al., 2018).

The increasing use of these elements in industrial applications and their high content in the waste from electrical and electronic equipment (e-waste) could represent another contribution to the concentration of lanthanides in soils and in the environment in general (Brewer et al., 2022). Unregulated disposal of technological items and uncontrolled recycling attempts may become sources of lanthanides in soils, especially in urban areas, the cores of the Technosphere.

The ever-growing demand for lanthanides for technological applications implies an increase in mining and production activities that may lead to adverse environmental and health effects. Mining operations can release dust containing REEs, other toxic metals and chemicals into the surrounding soil, water bodies and impact wildlife and vegetation in addition to humans. In general, the concentrations of lanthanides in bulk rock or ore are up to four orders of magnitude higher than those observed in soils. Therefore, the latter may be comparable to, or even higher, than those of rocks if the soils are in the vicinity of mining sites (not necessarily lanthanides mining sites) or plants where rocks or ores are processed such as phosphorites processing plants. In these areas, weathering of dumps and tailings accumulated during excavation or mineral processing (and containing trace amounts of

lanthanides) can be responsible for the critical accumulation of lanthanides in soil and the spread of contamination to other environmental compartments. This is the case concerning the largest known deposit of lanthanides in China, where the elements are dispersed in soils, sediments and waters of the adjacent area (Zhou et al., 2020). Similarly, the disposal of tailings in coal mining operations in Brazil favored the dispersal of lanthanides and their accumulation in soybean (*Glycine max* (L.) Merrill) plants cultivated in the surrounding areas (Galhardi et al., 2020).

The mobility of lanthanides in soil depends on the properties of the elements and the properties of the soil. Their chemistry in soil is similar but there are slight differences in hydrolysis and complexation constants, and in the resistance to weathering of the lanthanide-bearing minerals that result in fractionation and differential migration potential. In general lanthanide mobility is low, apart from some leaching of the light elements (lanthanum through gadolinium) and a relative enrichment of heavy elements (terbium to lutetium).

Lanthanides in the soil profile would show relations with the reactive components such as clay, carbonates, organic matter, aluminum (Al), iron, and manganese (Mn) and chemical properties such as pH, redox potential and cation exchange capacity. Similar to other soil metallic elements, their solubility increases with decreasing pH and with increasing redox potential (Mihajlovic and Rinklebe, 2018).

Lanthanides seem to have a particular affinity for organic substances and iron–manganese oxides. They form complexes with various organic (e.g., humic and fulvic acids) ligands often have coordination numbers exceeding 6, and sometimes as high as 12 (Gwenzi et al., 2018). Sorption of lanthanide on the surface of Fe oxides increases with increasing pH as the charge of the oxide becomes increasingly negative. Their affinity with Fe–Mn oxides makes them prone to being released when the oxides are solubilized under anoxic soil conditions. It has been reported that the availability of La, Ce, Gd, and Y increases with a decrease in pH and redox potential (Gwenzi et al., 2018).

In an experiment with two soils of different mineralogy and texture, Dinali et al. (2019) observed that sorption of lanthanides was similar in both soils at their original pH but increased with increasing pH two-fold in the Mollisol compared to the Oxisol. The differences in sorption were explained in terms of mineralogy, 2:1 clays vs oxide respectively, and organic matter content. Sorption was particularly influenced by soil pH for Oxisols, in which minerals with pH-dependent charge dominate.

Analogous results have been obtained by Rogova et al. (2020). They spiked soddy-podzolic and Chernozem soils, both rich in organic matter, with La, Ce, and Nd and found that fixation of the elements in the form of metal–organic complexes was predominant for both soil types (35–38% in podzolic soil and 50–79% in Chernozem) with respect to the exchangeable, specifically sorbed or Mn bound fractions.

Liu et al. (2022) undertook to remediate mine tailings by the addition of amendments and cultivation of plants, and observed a significant increase in pH and nutrients, which led to a decrease of 80–90% in soil-extractable lanthanides. They identified pH, and total C, N, and P among the most important factors controlling the availability of soil lanthanides.

Pathways by which lanthanides migrate in soil include plant uptake, erosion, leaching of lanthanide–inorganic complexes, organic complexation, eluviation of clay, precipitation reactions, and adsorption by phyllosilicates and oxyhydroxides of Fe and Mn.

Geochemical fractionation studies suggest that the bioavailability of lanthanides is relatively low while the residual fraction is relatively high which mean that their translocation in plants is difficult to establish. Gwenzi et al. (2018) reported that several studies indicated a preferential accumulation of lanthanides in the roots of plants. Results collated by Khan et al. (2017) showed an inconsistent picture where some plants may accumulate lanthanides while others preferentially translocate other elements. Some plants were observed to be hyperaccumulators of lanthanides such as *Carya tomentosa* Nutt. (Mockernut hickory) *Pronephrium simplex* Holtt., and *Dicranopteris dichotoma* Bernh. (Old World forked fern). Carpenter et al. (2015) reported large concentrations of Dy (dysprosium), Er, Nd, Pr, Sm, and Tb in roots of native plants *Asclepias syriaca* L. (common milkweed), *Desmodium canadense* (L.) DC. (showy tick-trefoil), *Panicum virgatum* L. (switchgrass) growing on contaminated soils. More recently *Phytolacca americana* L. (pokeweed) was found to accumulate lanthanides and has been proposed for the phytoremediation of contaminated sites and even the recycling of lanthanides (Yuan et al., 2018). The specific pattern of lanthanides uptake by plants has also been applied to establish the possible traceability of some food products, wine in particular (Bronzi et al., 2020; Barbera et al., 2021).

Actinides

Actinides are elements whose isotopes are all radioactive and are listed in Table 2. The presence of actinium (Ac), protactinium (Pa), uranium (U) and thorium (Th) in nature is because the semi-transformation periods of the ^{235}U , ^{238}U and ^{232}Th isotopes are long enough to ensure that these species are still present today. However, only thorium and uranium are widespread in nature.

It is essential to take into account the electronic configuration of the ground state of the actinides (Table 2) and the competition between the configurations $5f^n 7s^2$ and $5f^{n-1} 6d 7s^2$ to understand their chemical behavior and to compare it with that of lanthanides. Actinides, especially the first elements of the series, namely Th, Pa, U, Np, Pu, and Am, exhibit a greater tendency to provide more bonding electrons and, consequently, to give higher oxidation states than lanthanides. This is because the promotion of an electron from the $5f$ to $6d$ orbital requires less energy than that required for the promotion of an electron from the $4f$ to $5d$ orbital. The second half of the actinide series, namely Cf, Es, Fm, Md, No, and Lr, have chemical characteristics more similar to the lanthanides. The energies of the orbitals in the actinides are similar over a certain range of atomic numbers (especially from U to americium (Am)) and, because the orbitals overlap spatially they are all available to form bonds. This situation is highlighted

Table 2 Actinides and their properties.

Z	Symbol	Name	Electronic configuration	Oxidation ^a states

^aBold numbers represent the most stable oxidation state.

in the chemical properties by the fact that actinides have a greater aptitude to form complexes than lanthanides with their almost exclusively ionic bonds.

Uranium and thorium are primordial radioactive elements and are ubiquitous in the Earth's crust. The uranium concentration in the Earth's crust is about 2.4 mg kg⁻¹. Typical concentrations of uranium range from 1 to 10 mg kg⁻¹ in sandstone, shale or limestone, whereas granite contains up to 15 mg kg⁻¹ uranium. Uranium exists in the environment in the form of tetravalent (U⁴⁺) or hexavalent (U⁶⁺) oxidation states. The solubility of U in water, and hence its mobility in the lithosphere and potential for water pollution, depends strongly on its oxidation state and the presence of organic chelators. The U(VI) is the most common form in soil (80–90%) as the uranyl (UO₂²⁺) cation, and it is also the most mobile form of U. It exists in solution predominantly as the stable ion UO₂²⁺ and as soluble carbonate complexes. The uranyl cation is the main species responsible for U toxicity in aquatic organisms. Within the pH range of 4.0 and 7.5 and in the absence of dissolved inorganic ligands (carbonate, fluoride, sulfate, and phosphate), the hydrolysis species UO₂OH⁺, UO₂(OH)₂, and (UO₂)₂(OH)₂²⁺ dominate the U(VI) speciation. However, uranium in soil and water forms complexes with sulfate and phosphate as well as with carbonate and hydroxide. These complexes increase the total solubility of U. The U(IV), which is present under anoxic conditions, has a much lower solubility than U(VI) (Merian et al., 2004).

Uranium mining, processing of uranium ores, application of fertilizers, production and disposal of radioactive materials and recycling of spent nuclear fuel are the main sources of ²³⁵U. Emissions of uranium during mining and processing are generally low. Significant increases above natural levels may occur in local aquatic systems. Uranium in the hexavalent state is easily susceptible to migration in water while tetravalent uranium is immobile and stays in the soil itself. Infiltration of rainwater and subsurface flow may carry significant amount of uranium from the rocks and soils, which is then redistributed in the surrounding subsurface environment (Fig. 3). In general, groundwater was found to have a larger uranium concentration than the other fresh water sources because of prolonged residence time in the aquifers with rocks and soils containing uranium. However, the presence of uranium in water systems could also be due to the anthropogenic activities listed above. Intake of drinking water with a high concentration of uranium for a long duration can cause health effects such as kidney damage, cancer, increase in defective births, early graying of hair and cardiovascular diseases. Military uses (fission bombs based on ²³⁵U) and accidental releases of radionuclides such as during the Chernobyl accident may lead to the contamination of large areas. However, the contribution of uranium and its decay products to the radiotoxicity of nuclear fallout is marginal. Most of the acute and protracted dose is caused by relatively volatile and soluble fission or activation products such as ¹³¹I, ⁹⁰Sr, ¹³⁷Cs, or ¹⁴C with short, intermediate and long half-lives of 8 days, 29 years, 30 years, and 5730 years, respectively.

The Earth's crust contains about 13 mg kg⁻¹ thorium, as a constituent of more than 100 minerals. Abundance is comparable to that of beryllium and cobalt, and three times more than that of uranium. Typical concentrations range from 1 to 10 mg kg⁻¹ in sandstone, shale or limestone, whereas granite contains up to 80 mg kg⁻¹ thorium. Monazite, an orthophosphate of rare earth and other elements, may contain up to 28% Th oxide (Alloway, 2013).

These elements were produced in supernova synthesis and, therefore, they are indicators of geochemical processes and can be used to identify the origin of soil or rocks. Anthropogenic sources of these elements include mainly waste generated in coal-fired power plants and nuclear energy processing plants, where natural radionuclides of U and Th are used as a fuel. These elements may leach from rocks, soils and waste generated over time by industrial processing of naturally occurring radioactive materials (NORM), and transfer to humans through the food chain. Hazardous effects due to U and Th radionuclides in biological systems are well

Fig. 3 Uranium in European soils. Source: European Atlas of Natural Radiation Online version. ISBN 978-92-76-08258-3. doi:10.2760/46388, Catalogue number KJ-02-19-425-EN-N.

documented (IAEA, 2010). In particular, ^{232}Th and long-lived uranium isotopes ^{235}U and ^{238}U are both chemotoxic and radiotoxic, whereas all other isotopes and decay products are dominated by their radiotoxicity due to the ionizing radiation emitted during their radioactive decay. This is the result of the inverse relationship between the specific radioactivity (Bq kg^{-1}) and the half-life of a radionuclide. Since ionizing radiation has the potential to damage the genome, either directly or through ions and radicals generated in the vicinity of DNA, all substances emitting ionizing radiation must be considered mutagens and carcinogens. Moreover, for humans and animals, uranium and its salts are also highly chemotoxic. Dermatitis, kidney damage, acute arterial lesions, cancer, and cardiovascular diseases may occur. Finally, uranyl compounds readily complex with the phosphate-containing mineral matrix of bone.

The determination of concentrations of U and Th in environmental samples, mainly in soils, is required as background data to estimate their contamination level compared to natural abundances. Moreover, it is important to quantify the transfer of radionuclides from soil to plants by the transfer factor (TF), which is defined as the ratio of activity concentration of a radionuclide in dry plants to that of the same radionuclide in dry soil. The TF varies with the type of plant and radionuclide, from site to site and by season. These variations depend on several factors such as physical and chemical properties of the soil, environmental conditions, and the chemical forms of the radionuclide in soil (Saenboonruang et al., 2018). Soil properties that affect the absorption of radionuclides can include mineral and soil structure, organic matter content, pH and fertility.

The distribution coefficient (K_d) of radionuclides in the soil-solution system is an important parameter that expresses the ability of these elements to migrate in groundwater (Sheppard et al., 2006). It is defined as the ratio of the concentration of the element in the solid (soil) phase divided its concentration in the liquid phase (water) at equilibrium, usually expressed as L kg^{-1} . The K_d value is influenced by various physicochemical properties of soils such as soil texture, pH, carbonates (CaCO_3), cation exchange capacity (CEC) and chemistry of the transporting groundwater. For this reason, it is difficult to derive generic K_d values for radionuclides. The K_d values are usually estimated for site-specific conditions. Indeed, TF and K_d of artificial and natural radionuclides were calculated for different soils. However, the large variation in U K_d values reflects a strong dependence on soil properties, especially pH.

Numerous studies have attempted chemical fractionation of U and Th using sequential extractions. Each fraction corresponds to chemical forms of the elements, namely exchangeable (extractable with MgCl_2), which bond to the carbonates (extractable with CH_3COONa with CH_3COOH), bond to organic matter (extractable with $\text{CH}_3\text{COONH}_4$), bond to oxides (extractable with $\text{NH}_4\text{C}_2\text{O}_4$ and $\text{H}_2\text{C}_2\text{O}_4$) and residual (representing the radionuclides strongly bound to soil particles). Typically, the so-called 'exchangeable' and 'carbonate-bound' fractions are recognized as readily available (Rout et al., 2016). As a complement to chemical extractions, isotopic dilution assays have the potential to add new insights into time-dependent changes in U speciation. The technique involves adding a known amount of an isotopic tracer to a soil suspension in equilibrium; the resulting change in isotopic ratios gives an indication of the isotopically exchangeable concentration, which provides a more mechanistically based estimate of the reactive pool (Young et al., 2005).

All this information (TF, K_d , chemical fractionation and speciation) is of paramount relevance in the context of radioecological environmental contamination assessment and management. Is this a basis for better management of contamination?

Radon

Radon (^{222}Rn) is a radioactive gas produced by the decay of radium (^{226}Ra), which is a decay product of uranium and thorium in the uranium series (The series begins with naturally occurring ^{238}U and includes astatine, bismuth, lead, polonium, protactinium, radium, radon, thallium, and thorium). Radon is potentially mobile and can diffuse through rock and soil to escape into the indoor and outdoor atmosphere. Uranium is ubiquitous in rocks and soils, and Rn emissions vary according to the specific mineralogical composition.

Radon atoms are short lived, having a half-life of 3.8 days but are considered to be the most significant contributors to human exposure from natural sources. Inhalation of the gaseous radioactive isotope ^{222}Rn causes concern because it has been connected to lung cancer (Abrahams, 2002). Epidemiological studies on humans pointed out that up to 14% of lung cancers are induced by exposure to low to moderate concentrations of radon (Ćujić et al., 2021).

The gas emitted from fractured or porous rocks can easily move through the soil into the air before decaying. Radon can be a component of soil gas and enter and accumulate in houses by diffusion, determined by the difference in pressure between the house and soil beneath.

Not all radon produced in this process moves into soil pores. The number of radon atoms released per the number of radon atoms generated is known as the emanation fraction. The amount of Rn escaping to the atmosphere varies greatly as a function of the geology (e.g., U content and chemical form, degree of jointing or faulting), soil characteristics (e.g., permeability, moisture content) and climatic variables (e.g., temperature, humidity) (Oliver and Khayrat, 2001). The highest concentrations of uranium are found in granites (Ćujić et al., 2021). The emanation fraction is inversely proportional to the sizes of the soil particles in relation to their associated surface areas. Furthermore, soil moisture influences the emanation fraction by reducing the speed of radon atoms and preventing them from embedding in another particle.

Averages of the radon emanation fractions determined from minerals, rock, soil (1025 samples), mill tailings (77), and fly ash (46) were found to be 0.03 (range 0.00–0.25), 0.13 (0.00–0.40), 0.20 (0.00–0.83), 0.17 (0.04–0.35) and 0.03 (0.00–0.35) respectively. The Rn emanation fractions vary considerably even for the same materials (Sakoda et al., 2011).

Sometimes local soils can contribute to elevated outdoor ^{222}Rn concentrations, and such exposure needs to be included in epidemiologic studies.

Recent studies in the tectonically active Himalaya area (Kumar et al., 2022) found an average radon concentration in soils of up to $4969 \pm 561 \text{ Bq m}^{-3}$ and a radium content of 51.04 Bq kg^{-1} . Similarly, Walat and Khairi (2021) reported a mean soil depth activity of ^{222}Rn and ^{226}Ra in the Duhok district of Iraq of $305 \pm 44 \text{ Bq m}^{-3}$ and $33 \pm 5 \text{ Bq kg}^{-1}$ respectively.

The contribution of uranium mining to contamination of the surrounding environment is depicted in a study by Huang et al. (2021). They reported a maximum activity concentration of ^{238}U and ^{226}Ra near a mine in China of 5600 Bq kg^{-1} and 4791 Bq kg^{-1} , respectively. Similar results were also obtained by Komati et al. (2021) in soils around a gold mine in South Africa.

Radium may be taken up by plants, as observed by Parekh et al. (2008) in nuts grown in various localities of South America. Radium concentrations in nuts grown in the four regions were similar: ^{226}Ra ($17\text{--}27 \text{ mBq g}^{-1}$) and ^{228}Ra ($18\text{--}31 \text{ mBq g}^{-1}$), suggesting that the amounts in the nuts were influenced by bioaccumulation rather than soil content.

Several countries around the world have adopted regulations to control exposure to radon in indoor environments. In Europe (Fig. 4), a guideline value for ^{222}Rn indoor concentration of 300 Bq m^{-3} has been recommended for the European Union Member States (Directive 2013/59/Euratom).

Analogously, the World Health Organization indicates a reference level possibly lower than 100 Bq m^{-3} and not higher than 300 Bq m^{-3} . In Italy, a survey by the National Institute for Environmental Protection and Research (ISPRA) and the Italian National Institute of Health (ISS) provided an estimate of the average national value of indoor ^{222}Rn of about 70 Bq m^{-3} which is well above the worldwide mean of about 40 Bq m^{-3} (Guarino et al., 2022). In the UK, Cornwall and Devon are particularly affected by radon; they have 53% of UK homes that are estimated to contain a concentration of ^{222}Rn above the 'action level' of 200 Bq m^{-3} (Abrahams, 2002). This is possibly related to the areas with granite exposed at the surface or close to it.

Fig. 4 Indoor Rn map of Europe. Source: European Atlas of Natural Radiation Online version. ISBN 978-92-76-08258-3. doi:10.2760/46388. Catalogue number KJ-02-19-425-EN-N.

Conclusions

The technological evolution of human activities has brought about this trail of new contaminants. At the same time the advances of analytical techniques have facilitated the recognition of actual and potential threats to the health of humans and of the environment.

In general, it is evident that the research effort in this field has progressed, but it is far from obtaining a clear picture of the environmental significance of radon, lanthanides and actinides. Monitoring of these contaminants becomes indispensable if the ecosystem is to be protected.

Abstract

Among all halogens fluorine (F) and chlorine (Cl) have the highest concentrations in soil followed by bromine (Br) and iodine (I). The variability of halogen contents in soils is high, which depends to a major degree on atmospheric deposition (Cl, Br, I), parent material (F), organic matter (Cl, Br, I), secondary minerals (F, Br), and local pollution (F, Cl). The enzyme-mediated reaction between halide ions and organic matter known as halogenation is considerable in some soils for Cl, Br and I, and should be accounted for in future ecosystem halogen budgets.

Key points

- Br, Cl and I act similarly in soil through the coexistence of two main pools: inorganic and organic. However, each pool seems regulated by cycles operating on different timescales.
- The main pool of fluorine is minerals in soil. The loss of dissolved F from soil is constrained by the strong sorption to pedogenic oxides probably via inner-sphere substitution reactions between OH^- and F^- .
- Chloride dominates import and export from soil while organically bound Cl can dominate the standing stock Cl.
- Among the four halogens, bromine takes an intermediate position in terms of mineral and organic pools, and also of the fluxes of sorption, halogenation and leaching.
- The strong biophile nature of iodine promotes its association with soil organic matter compared with the other halogens.

Introduction

The halogens are a family of elements in group 17 (VIIA) of the periodic table, consisting of six elements: fluorine (F), chlorine (Cl), bromine (Br), iodine (I), astatine (At), and tennessine (Ts). Out of all halogens, there are no stable (non-radioactive) isotopes of At and Ts and therefore, At and Ts are not present in soils. The name 'halogen' was proposed by Jöns Jakob Berzelius in 1842 based upon the Greek words 'hal' (salts) and 'gen' ("to produce"). The halogen atoms have seven electrons in their outer shells, so that the addition of only one electron gives the corresponding anions (halide ions) a stable electron configuration and an oxidation number of -1 (Table 1). The specific chemical properties of halogens are often referred to as reactive, and thus they are never found in their monatomic form, but rather as part of other compounds. Therefore, all halogens are oxidizing elements and F, followed by Cl, is the most electronegative.

Halogen geochemistry has been well documented in general (Fuge, 2019; Schlesinger et al., 2020) (F), (Graedel and Keene, 1996) (Cl), (Fuge and Johnson, 1986) (I). Contrary to old reviews stating that halogens are more or less inert in soils, i.e., few halogens interact in any biological processes, it is now clear that several biogeochemical processes control the fate of the halogens (Svensson et al., 2021) (Cl), (Fuge and Johnson, 2015) (I), (Epp et al., 2020) (Br).

There is scattered information on the abundance of halogens in soils, of which F and Cl are the most reported. Average contents in soil are approximately 321 and 300 mg kg^{-1} for F and Cl, respectively, and 10 and 2.8 mg kg^{-1} for Br and I, respectively

Table 1 Selected properties of halogens.

Property	F (Fluorine)	Cl (Chlorine)	Br (Bromine)	I (Iodine)
Atomic number	9	17	35	53
Atomic mass	18.99	35.42	79.90	126.90
Atomic radius	57	97	122	132
Valence	-1	-1	-1	-1
Electronegativity (eV)	3.9	3.0	2.8	2.5

(Kabata-Pendias, 2011). The variability of halogen contents in soils is considerable and is to a major part due to distance to the coast, parent material, organic matter, secondary minerals, and local pollution. The most commonly used methods for estimating soil contents rely on measuring the soluble inorganic forms or the total content of halogens only, while ignoring the transformation of halogens between inorganic and organic forms which is considerable in some soils for Cl, Br and I.

Fluorine in soils mostly originates from natural processes such as atmospheric deposition and weathering resulting in their release from F-bearing minerals in rocks (Fuge, 2019; Schlesinger et al., 2020). Nevertheless, atmospheric fluxes of F are dominated by anthropogenic sources (55%), such as brick manufacturing, and the mining of P-containing rocks for phosphate fertilizer production. Anthropogenic atmospheric fluxes have tripled since preindustrial time (3.2–9.7 Tg F yr⁻¹; Schlesinger et al., 2020). Though the uptake of F by plants is reported to be small, it is important to monitor the concentrations of fluorinated compounds in plants and groundwater to be able to maintain safe levels for human and livestock intake. As the fluxes to soils are dominated by anthropogenic sources, the main interest in F for soils has been on pollution control and remediation (environmental chemistry, food production).

Chlorine is in general as common as F in soils and its major source in soils is by atmospheric deposition. Thus, there is a strong gradient of decreasing soil Cl concentrations from coast to inland. The general view is that chloride is the dominant form of Cl in ecosystems, but in soils, about 50% could be organically bound, and the storage of Cl in the pedosphere has been estimated to contain 48 Pg Cl (Graedel and Keene, 1996; Svensson et al., 2021). Chlorine in soils has been of interest from multiple perspectives, including the use of chloride as a tracer for sub-surface water flow and contaminant transport (hydrology), organochlorine pollutants and salinization (environmental chemistry), Cl cycling (biogeochemistry, soil sciences), radioactive waste (radioecology; ³⁶Cl is of great concern), and biology (plant science; Cl as an essential element for functions of living plants). During the past decades there has been a rapid development towards improved understanding of the terrestrial Cl cycle (Lovett et al., 2005; Bastviken et al., 2009; Tanaka and Thiry, 2020).

Bromine has received little attention compared to F and Cl due to its small background concentrations in soil. For a long time, Br had been assumed to sorb weakly to soil particles and thus to be less reactive than F and Cl. This conservative behavior enabled its application as a tracer (Levy and Chambers, 1987). However, the assumption of its conservative behavior was challenged because, for example, the correlation of Br and organic matter suggests a retention mechanism in soil (Leri and Myneni, 2012). As a consequence of the artificial synthesis, organobromine compounds have been released into the environment. Thus, a major focus has been on anthropogenic sources although natural bromination processes are also occurring (Leri and Myneni, 2012). Whereas Cl, I and probably F are essential elements for human and animal nutrition, no function has been identified for Br. However, in view of its ubiquitous occurrence in the biosphere, Br may well have some function in animal health and more research is needed to explore this possibility.

¹²⁷Iodine, the only stable isotope of I, is an essential element for humans and higher animals while ¹³¹I and ¹²⁹I are of potential concern since they may be contaminants from accidental nuclear release and the storage of radioactive waste, respectively. Seawater is rich in stable I which can be volatilized and transported to the atmosphere resulting in marked enrichment in near-coastal soils. The content of I in soils is thus in large part due to its atmospheric input, but also due to geological and edaphic conditions (Fuge and Johnson, 2015). Human intake of stable I is mainly from food, but some populations also obtain substantial quantities of I from drinking water. Most agricultural topsoils and irrigation water contain very small concentrations of I. Moreover, the bioavailable forms IO₃⁻ and I⁻ in soil may be limited by leaching, strong sorption or their volatilization. Thus, plant-derived dietary I may be insufficient, and deficiency still affects many people around the world. Methods to improve the uptake of I by plants and its accumulation in edible parts are still at an early development stage (e.g. Izydorczyk et al., 2021).

Fluorine in soils

Fluorine (F) is the lightest element of the halogen group and has the largest electronegativity compared to all other elements. Accordingly, -1 is the only stable oxidation state of F. It is a monoisotopic and mononuclidic element with ¹⁹F being the only isotope that is present beyond trace quantities.

In the crust, F is the most abundant halogen with average concentrations of 575 mg kg⁻¹. Because of the similarity in the ionic radii, hydroxyl groups (OH) can be readily substituted by F in the crystal lattice of silicates and apatite (fluorapatite: Ca₅(PO₄)₃F). In addition, F is present in the crystal lattice of fluorite (CaF₂) and topaz (Al₂SiO₄(F, OH)₂). Most of these F-containing minerals are sparingly soluble. Igneous rocks containing CaF₂ and shales have the highest F concentration while sedimentary rocks mostly contain <300 mg kg⁻¹ F (Fuge, 2019; Schlesinger et al., 2020). The concentrations of F in sedimentary phosphorites is two orders of magnitude higher because they contain carbonate fluorapatite (Schlesinger et al., 2020).

Globally, soils contain on average 321 mg F kg⁻¹ (Kabata-Pendias, 2011). The lowest concentrations occur in Arenosols, Podzols and Histosols and the highest in Cambisols (Kabata-Pendias, 2011). This difference can be attributed to clay and organic matter contents (Pickering, 1985). Furthermore, weathering and leaching during other or paleo climates may have influenced local soil F concentrations. The F concentrations in non-contaminated soils are commonly less in top- than in sub-soil (Epp et al., 2020; Neidhardt et al., 2022). In general, F concentrations are lower in soil than in the parent material suggesting loss of F during soil formation.

In contrast to the other halogens, the loss of F during soil formation cannot be explained by gaseous emissions. The emission of gaseous F compounds is restricted to anthropogenic manufacturing processes (see below) or natural processes involving high temperatures (Schlesinger et al., 2020). Therefore, there is no loss of gaseous F compounds from soil. The leaching of F is supposed

to be low because most primary and secondary F-bearing minerals in soil have a low solubility (Pickering, 1985). Accordingly, only ca 1% of total F in soil is water-soluble (Epp et al., 2020; Neidhardt et al., 2022) and F concentrations in the soil solution are mostly $\ll 1 \text{ mg L}^{-1}$ (Epp et al., 2020). Nevertheless, leaching was inferred from the smaller F concentrations in topsoil compared to the subsoil and, from the decrease of F concentrations in soil with increasing precipitation. Particularly in acidic soils, leaching is fostered by the formation of labile fluoro-iron (Fe(III)) or fluoro-aluminum (Al) complexes that increase the dissolution of F-bearing minerals and the desorption of F^- by the concomitant dissolution of the sorbing agents, namely Fe/Al (oxy)hydroxides (Pickering, 1985). In calcareous soils, slow rates of adsorption can result in rapid leaching. Leaching might also comprise water-soluble organofluorine compounds (Pickering, 1985).

Leaching loss from soil might be counterbalanced by external input and retention of F. Depending on the distance to the sea, marine-derived wet deposition of F might be important although the marine origin is controversial (recently reviewed by Fuge, 2019). In Norway, wet deposition of F ranges between 0.89 and $168 \text{ mg m}^{-2} \text{ yr}^{-1}$. Assuming an average F concentration of 0.02 mg L^{-1} in rainfall of remote regions (Schlesinger et al., 2020), wet deposition would result in a range of $1\text{--}30 \text{ mg F m}^{-2} \text{ yr}^{-1}$ for sites in southwestern Germany and Chile (Epp et al., 2020; Neidhardt et al., 2022). In addition, wind-blown dust from soil that forms part of the dry deposition needs to be included as an atmospheric input. However, the dry deposition flux of F to ecosystems has not yet been quantified. As F^- is the smallest ion among the halogens, it is strongly sorbed to charged surfaces in the soil matrix. In line with this, F has the fastest kinetics and the greatest sorption capacity compared with the other halide ions on model minerals (Fe and Al oxides, kaolinite) and in soil (Pickering, 1985; Chubar et al., 2005). Sorption of F^- comprises substitution reactions between OH and F in secondary minerals such as pedogenic oxides (metal (oxy)hydroxides) and clay minerals (Pickering, 1985). Metal hydroxides in soil e.g., $\text{Al}(\text{OH})_3$, and amorphous, poorly ordered hydrous oxides of Al were shown to be more important than clay minerals for such substitution reactions (Pickering, 1985). The increase in sorption of F^- with soil depth was attributed to an increase in sorption capacity and a decrease in desorbability. The fluorination of organic matter is another retention process. However, the large electronegativity of F results in a very large reduction potential ($E^0 = +3.06 \text{ V}$) and thus, constrains enzyme-catalyzed reactions (Carvalho and Oliveira, 2017). For a long time, no enzyme capable of fluorination had been known. Only recently, a natural fluorinase enzyme, the related organofluorine biosynthetic gene cluster and the fluorination mechanism were revealed in the soil-dwelling bacterium *Streptomyces cattleya* (Carvalho and Oliveira, 2017). Although more than 5000 biogenic organohalogens have been identified to date, only about 30 fluorinated organic compounds of natural origin e.g., fluoroacetate (FA), ω -fluoro-fatty acids and nucleocidin, have been discovered in the environment (Carvalho and Oliveira, 2017). Biologically produced, natural organofluorine compounds contain only one F atom (Carvalho and Oliveira, 2017). Abiotic processes linked to volcanic activity might also produce organofluorine compounds such as fluorotrichloromethane, trifluoropropene or fluorobenzene (Carvalho and Oliveira, 2017). Although the C—F bond is extremely stable (Schlesinger et al., 2020), defluorination might occur.

Anthropogenic activities influence the abundance of F in soil. For example, the manufacturing of bricks from clay-rich raw materials and the mining and processing of phosphate rock (fluorapatite deposits) used as fertilizers are the two largest sources of emission of gaseous F-containing compounds (e.g., HF and SiF_4) in the atmosphere (Pickering, 1985; Fuge, 2019; Schlesinger et al., 2020). Another emission source is Al smelters (Fuge, 2019; Schlesinger et al., 2020). Gaseous emissions of HF and SiF_4 affect F concentrations in soil as illustrated by greater soil F concentrations in the proximity compared to more distant locations from the Al smelters. In addition, phosphate rock contains 1.5–4 mass% fluoride and is applied as a fertilizer directly to the soil (Loganathan et al., 2001). With larger inputs, this might (Loganathan et al., 2001) or might not result in increased F concentrations in soil in the long run. For example, F applied as fertilizer was reported to be retained in topsoil (Loganathan et al., 2001) but did not pose a risk for surface water contamination. Furthermore, man-made organofluorine compounds are now other ubiquitous contaminants in the environment including soils, but biodegradation of many of these compounds is unknown (Carvalho and Oliveira, 2017).

The sorption of organofluorine compounds in soil requires further research given its influence on the persistence of natural and man-made organofluorines in the environment. Because of the large anthropogenic contribution (>55%) to atmospheric F fluxes (Schlesinger et al., 2020) combined with long-distance transport of F in the atmosphere, the anthropogenic impact on the fate of F in soils means that it probably reaches remote regions in the world. In addition, the application of rock-phosphate derived fertilizers around the globe and the transport of F in particulate form from arable fields to surface waters by soil erosion (Schlesinger et al., 2020) complicates the study of the natural biogeochemical cycle of F.

Chlorine in soils

Chlorine (Cl) is one of the 20 most common elements on earth. Its atomic number is 17 and it has a very high electron affinity and electronegativity, thereby molecular Cl is a strong oxidant. Consequently, molecular Cl is rare in nature and instead the inorganic ion form, chloride, which is highly soluble in water, typically dominates in the hydrosphere and in minerals. Chlorine occurs in nature as primarily two stable isotopes, ^{35}Cl (ca 76%) and ^{37}Cl (ca 24%). In addition to these, seven radioactive isotopes exist of which ^{36}Cl has a very long half-life, 3.01×10^5 years. Chloride in soil has traditionally been associated with soil salinity and toxicity for plants, though there are many studies on Cl that suggest it is essential for life for various reasons.

The largest Cl reservoirs on the earth surface are the crust and the ocean (Graedel and Keene, 1996). Inorganic Cl (chloride) by far dominates these reservoirs. Estimates for the reservoirs are largely based on chloride concentration measurements. This assumption of a general dominance of chloride is problematic for the pedosphere because organically bound Cl has been shown to range from 11 to almost 100% of the total Cl pool in a large range of soil types (Redon et al., 2013). In deeper mineral soils >80% of the Cl seems to be organic. This means that the pedosphere Cl pool may be at least twice as large as was proposed by Graedel and Keene (1996).

Total Cl contents typically range from 20 to >1000 mg Cl kg⁻¹ in non-saline soils (Svensson et al., 2021). The concentrations of organically bound Cl in surface soil layers are greater than chloride levels in most cases. The dry weight fraction of organically bound Cl in surface soils (0.01–0.5%) is comparable to naturally occurring concentrations of several important nutrients, including phosphorus (0.03–0.2%), nitrogen (1–5%) and sulfur (0.1–1.5%). In forests, the total storage of organically bound Cl is usually larger in the mineral soil layer than on the forest floor because of smaller Cl concentrations in mineral soil, but larger thickness and bulk density of mineral soil (Redon et al., 2013). The available data, primarily from dry forest soils but also a few agricultural soils, indicate that total Cl concentrations are highest in soils with more organic matter and the percentage Cl_{org} is frequently above 80% in humus (Svensson et al., 2021 and references therein).

It should be emphasized that the available information is based on a limited number of studies and general patterns as well as the chemical complexity of the organically bound Cl are scarce. In a sandy loam soil (organic matter content of approximately 4%), the organically bound Cl was associated with organic matter with a molecular mass <10,000 Da, while most organic matter in the soil studied had a molecular mass >10,000 Da. The results suggest that most of the newly formed chlorinated organic matter in the soil studied was of low molecular weight.

More than 5000 chlorinated organic substances have been identified (Gribble, 2015). Naturally produced organically bound Cl is a diverse group, which contains simple alkane compounds, such as chloromethane, but also more complex forms as a result of, for instance, decomposition of plant material. Many of these have known anti-competitor functions, used by organisms to secure resources, and as antibiotics. For most of the compounds, the ecological function remains unknown. In addition, the concentrations of organically bound Cl in most soils are typically as large as, or exceed, the amounts of chloride, which indicates the likelihood of additional ecological functions for organically bound Cl.

Most of the studies on Cl biogeochemical cycling have hitherto focused on bulk soil in which plant roots were removed by sieving, even though vegetation and associated organisms have a strong influence on element turnover. Increased availability of labile organic matter and plant roots seems to increase the rates of formation of organically bound Cl. This indicates that increased rates of chlorination are to be expected when more organic matter is recycled and corresponds to the idea that chlorination is controlled by biotic activity and is highest in the surface soil layers with greater root density and more input of fresh organic matter.

A consistent pattern has shown that the concentration of organically bound Cl is higher in soils under coniferous forest than those covered by deciduous forest. In experimental forests, plots with Norway spruce (*Picea abies* (L.) H. Karst.) had the highest net accumulation of chloride and organically bound Cl over the experimental period of 30 years and showed 7- and 9-times greater storage of chloride and organically bound Cl, respectively, in the soil humus layer compared to plots with oak (*Quercus petraea* (Matt.) Liebl.) (Montelius et al., 2015). Similarly, Neidhardt et al. (2022) found the largest total Cl concentrations in the mineral soil of a coniferous forest comprising *Araucaria araucana* (Molina) K. Koch in Chile. Thus, it seems likely that vegetation characteristics may be one important factor to explain soil Cl concentrations and why the spatial variation may be independent of atmospheric deposition.

Within soils, many dynamic processes affect the cycling and leaching of Cl. These processes are primarily controlled by precipitation, but are also affected by vegetation, gaseous emission from the soil, and biochemical transformation in soil. It is generally assumed that most of the deposited chloride is transported through soil unaffected, with only a minor influence of soil adsorption by e.g. ion-exchange processes. Traditionally chloride is thought to be bound only electrostatically and therefore the binding is easily reversible, which results in rapid equilibration with the soil solution. As mentioned previously, chloride is easily dissolved in water and could percolate to groundwater and surface waters. However, significant percentages of organically bound Cl, 16–54% of the total Cl leached from topsoil. Though the estimates are based on laboratory studies, considerable Cl is probably transported as organically bound from topsoil. However, on a catchment scale the annual transport of Cl is dominated by chloride (Svensson et al., 2021). Using a modeling approach, Tanaka and Thiry (2020) estimated that fluxes in the annual organic cycle leading to net retention in soil concerned only small amounts of Cl circulating in the system. This also explains why imbalance between inflow and outflow from Cl transformation in soil is not easy to detect at large scales.

The output of approximately 2% of chloride from a small stream at Hubbard Brook experimental forest (NY, USA) has been estimated to originate from weathering bedrock consisting mainly of granite; this amount is small compared with the atmospheric contribution (Lovett et al., 2005). Montelius et al. (2015) measured the mineral-bound Cl in soil developed from granite, collected in Breuil-Chenue (Bourgogne, France); it was less than 12% of the total soil Cl.

There are indications that volatilization of Cl could be a significant export pathway of Cl from the soils. Volatile organochlorines (VOCl_s) are produced in a wide variety of ecosystems such as wetlands, salt marshes and forests and in different climatic regions. Budget and transport estimates on various scales are highly uncertain, partly because the small concentrations of each specific VOCl make sampling and analyzes challenging. Emissions are considered to be small compared to the wet and dry deposition of Cl. However, a ³⁶Cl radiotracer study indirectly indicated the substantial release of VOCl_s in soils corresponding to 0.18 g Cl m⁻² yr⁻¹ or 44% of the local annual wet deposition (Bastviken et al., 2009). This is a high number that needs validation, but interestingly it includes all possible VOCl_s in contrast to other estimates that measure specific VOCl compounds only. Previous studies showed average emissions of chloroform and chloromethane corresponding to 0.13 and 0.04 g Cl m⁻² yr⁻¹, respectively, from a coniferous forest soil (Dimmer et al., 2001). This suggests that the formation of VOCl would represent a significant part of Cl transformation in soil.

Studies in terrestrial environments have revealed that Cl is very reactive, which contradicts the previous view that chloride deposited on soil has a short residence time there (no interaction with soil minerals, microorganisms or roots and vegetation), and is quickly flushed to groundwater and eventually into the oceans. It is now evident that there is ubiquitous and extensive natural chlorination of organic matter in terrestrial ecosystems. Experimental research with radioactive ³⁶Cl as a tracer has confirmed extensive natural rates of chlorination corresponding to as much as 50–300% of the annual wet deposition of Cl in several types of

soils (Bastviken et al., 2009). Many organisms display an active metabolism involving halogens (Gribble, 2015), but the fundamental reasons for the halogenation are still unclear. Several alternative hypotheses have been suggested for chlorination processes including allelopathic processes, e.g., (i) defense against pathogens/competitors/parasites, (ii) formation of HOCl could either be a defense against reactive oxygen species that are formed as by-products in cellular metabolism, (iii) or a way for microorganisms to access refractory organic matter. Many of the haloperoxidase producing organisms are microorganisms associated with plants and animals (e.g., rhizosphere associated microorganisms, endophytes/endosymbionts and pathogens/parasites). Thus, dominating tree species, soil organic matter (SOM) content, humus type and soil pH seem to be important for the accumulation of Cl in soils. The new views of Cl have implications for research on Cl storage and dynamics in terrestrial ecosystems and landscapes, raising issues as to what is controlling the processes and what ecological functions are involved.

Bromine in soils

In the environment, bromine (Br) is mainly present in the most stable oxidation state of -1 but other oxidation states also exist (0 , $+1$, $+3$, $+5$ and $+7$). Apart from several radioisotopes, Br has two stable isotopes (^{79}Br , ^{81}Br). In the Earth's crust, Br is present in the crystal lattice of minerals of the apatite group, biotites and amphiboles at concentrations ranging from 0.6 to 15 mg kg^{-1} (mean: 1 mg kg^{-1} ; Kabata-Pendias, 2011). Probably because of adsorption to charged mineral surfaces, sedimentary rocks contain more Br than igneous rocks, though extrusive igneous rocks might also have large concentrations.

Globally, soils contain on average 10 mg Br kg^{-1} (Kabata-Pendias, 2011). There are a few compilations of Br concentrations in soil that cover different lithologies or climate zones (Gerzabek et al., 1999; Yamasaki et al., 2015; Neidhardt et al., 2022). For topsoils under agricultural use in Austria, Gerzabek et al. (1999) found a range of 2 – 12 mg Br kg^{-1} (mean 6 mg kg^{-1}) and soils on calcareous parent material had larger Br concentrations than those on non-calcareous parent material. Similarly, large Br concentrations were reported for soils developed on extrusive igneous rocks (Yamasaki et al., 2015). Br concentrations in Andosols (mean 37 mg kg^{-1}) were at least three times higher than for other soil types (range of means: 0.5 – 13 mg kg^{-1} for Podzols, Cambisols, Acrisols, Gleysols and Regosols; Yamasaki et al., 2015). Soils developed on intrusive igneous rock along a climate gradient from the arid Atacama Desert to the (super) humid temperate zone in Chile showed a range in Br concentrations between 2 and 64 mg kg^{-1} (Neidhardt et al., 2022). By far the largest Br concentrations were found in the humid zone (mean of 43 mg kg^{-1}) where soil formation was most advanced (soil type: Umbrisol; Neidhardt et al., 2022). Topsoils had larger Br concentrations than subsoils (23 and 6 mg kg^{-1} , respectively; Yamasaki et al., 2015). However, this pattern does not seem to be universally valid since the opposite was also observed (Neidhardt et al., 2022). In general, Br contents are larger in soil than in the parent material suggesting retention of Br during soil formation.

Soil enrichment in Br seems to be a combination of different biogeochemical processes comprising atmospheric deposition of Br, sorption of Br to charged surfaces of the soil matrix and bromination of organic matter. Bromide ions (Br^-) are the main component of atmospheric deposition of Br (Biester et al., 2004) ranging from 3 (Gilfedder et al., 2011; Epp et al., 2020) to $1.56\text{ g Br m}^{-2}\text{ yr}^{-1}$ (Biester et al., 2004). Organobromine species were found in rain and snow, but their contribution is commonly less than one third of Br in precipitation. After deposition, Br^- might be sorbed to charged surfaces in the soil matrix. The sorption capacity tended to be larger for Br^- than for Cl^- (Chubar et al., 2005) while similar sorption of Br^- and Cl^- was also reported. Bromide might also serve as a reaction educt for bromination of SOM which was shown to be favored over other halogenation reactions (Leri and Myneni, 2012). Similarly, Biester et al. (2004) found that Br enrichment was largest during peat decomposition among the halogens studied. Bromination can be catalyzed by the same enzymes as those for chlorination (e.g., chloroperoxidase; Leri and Myneni, 2012), but can also result from abiotic processes (Leri and Ravel, 2015). The majority of organobromine species in soil are monobrominated (Tang et al., 2022). Bromination might be the main factor for retention of Br in soils because organic matter concentrations are strongly correlated with Br concentrations in Japanese soils (Yamasaki et al., 2015), and organobromine species dominated over inorganic Br species in Andosol samples (Takeda et al., 2018).

Bromine can be released from soil by the emission of gaseous Br species, or the leaching of Br. Plants and soil microorganisms are known to emit methylbromide (CH_3Br) (Horst et al., 2014). Abiotic formation of CH_3Br was also suggested (Horst et al., 2014). The leaching of Br has not yet been systematically quantified. Assuming that about half of the precipitation is lost as seepage fluxes, Br^- leaching would amount to $15\text{ mg m}^{-2}\text{ yr}^{-1}$ in the temperate forest studied by Epp et al. (2020). The output of Br^- would be three times larger than the atmospheric deposition of Br^- at the site investigated (Epp et al., 2020).

Compared to the other halogens, fewer studies are available on the fate of Br in soil. Therefore, basic knowledge gaps exist regarding sorption mechanisms of Br^- , production of organically bound Br, and the release of dissolved organic Br. Similarly, we are not aware of any study that set up Br budgets to evaluate the accumulation versus the loss of Br in soil. Furthermore, the role of redox dynamics that potentially influence the speciation and mobility of Br has not been fully explored.

Iodine in soils

With an atomic number of 53 and an atomic mass of 127 , iodine (I) is the heaviest of the stable halogens. It has several main oxidation states (-1 , $+1$, $+3$, $+5$ and $+7$), and only one naturally occurring stable isotope (^{127}I). The admission of I into the crystal lattice of rock-forming minerals is hampered by the large size ($2.20\text{ \AA}$) of its anionic radius. That explains why I is less abundant than the other halogen elements in the Earth's crust, its average concentration is estimated to be about 0.3 mg kg^{-1}

(Fuge and Johnson, 2015) and 1.4 mg kg^{-1} for the upper crust, where sedimentary rocks commonly contain larger amounts than metamorphic and igneous rocks.

From a database of over 1500 soil samples collected at the European continent scale (De Vos et al., 2006), the calculated median I content is 3.9 mg kg^{-1} in topsoil (0–25 cm) and 3.4 mg kg^{-1} in subsoil (a 25-cm thick section sampled from 50 to 200-cm deep); values range from <2 to 70.8 mg kg^{-1} in topsoils and up to 92.5 mg kg^{-1} in subsoils. For French forest soils (50 sites), Roulier et al. (2019) reported a median concentration of 4.2 mg kg^{-1} , a value slightly higher than the median European concentration of 3.9 mg kg^{-1} for topsoil, but the concentration range (0.4 – 35.7 mg kg^{-1}) was quite similar. Of note is that in general median values for soils are much higher than the average of 1.4 mg kg^{-1} for the upper crust, suggesting that I enrichment in most soils does not originate from weathering of the rocks on which they developed but rather from retention of atmospheric deposits. Though, at local scale in regions characterized by limestone and chalk terrains, calcareous parent-rock represents a key reservoir of weathered I for soil or drainage water enrichment.

Iodine is a biophilic element, therefore, the behavior of both stable and radioactive isotopes in the environment is of great concern (Thiry et al., 2022; Neeway et al., 2019). The understanding of I behavior in terrestrial environments is complicated by intricate microbial, photochemical, physicochemical, and organic interactions, in vegetation and soil, leading to its release through volatilization and drainage, or to its accumulation through SOM iodination or sorption by various biological and mineral components; see Fuge and Johnson (2015), Kaplan et al. (2014) and Neeway et al. (2019) for recent reviews, and references therein.

The properties that most affect I retention in soils involve soil organic matter (SOM), Fe–Al oxides and pH (Fuge and Johnson, 2015). Iodine incorporation into SOM by the covalent aromatic C–I bond, usually at aromatic carbon sites, is a central mechanism controlling I retention; and this transformation may greatly limit the transport of I in soil on the time scale of SOM persistence. The adsorption of I anions by bonding to localized positive charges on the surface of metal oxides is likely to be higher at low pH.

Soil fractionation and extraction help in dividing soil I into operationally defined pools of different mobility. However, controls of individual soil properties on I retention in soils remain difficult to determine. For example, Roulier et al. (2019) reported larger I concentrations in soils with higher organic matter, total iron and aluminum concentrations, and with these three soil constituents being correlated. That observation prevented the identification of soil constituents that had the greatest statistical influence on the I concentrations in soils. This result is not surprising since efficient sorption of organic matter on metal oxides surfaces is well known; moreover, soils with higher organic matter content also tend to have lower pH. Inorganic I sorption onto oxide phases would have a minor impact on the rate of I incorporation into soil humic materials. The semi-mechanistic model proposed by Chang et al. (2014) supported the assertion that the organic I fraction is an important ultimate reservoir in soil; the I uptake coefficient for SOM is an order-of-magnitude greater than that for mineral surfaces.

The reaction of I with SOM resulting in the formation of non-soluble organically bound I is quite rapid and largely influenced by microbial activity. Iodine accumulation in the non-labile pool of a forest floor is believed to be controlled by a process of sorptive accumulation in addition to organic matter iodination, since soluble organic I represent a major fraction in rain and throughfall (Pisarek et al., 2022 and references therein). In addition to iodide (I^-), dissolved organic I also represents a major form of I in soil solution, its vertical mobility in the soil column is further influenced by the solubility and partitioning of organic carbon. Both the addition of I at the soil surface and its interaction with SOM normally lead to a gradual decrease of I content with soil depth that is concomitant with the organic matter content. In some cases, a peak of I can occur at soil depths of 15–45 cm. Pisarek et al. (2022) ascribed that peak to the occurrence of an I retention front resulting from the reaction of dissolved organoiodine with a layer enriched in secondary Al precipitates that are common in acid soils.

The sequestration of soil-bound organoiodine is only transitional; its remobilization, notably in the organic colloidal form, largely depends on the local SOM turnover. In addition, microbial deiodination of organoiodine may occur naturally in soil, usually under anoxic conditions. Overall, there is still a lack of information on the mechanisms and kinetics controlling the degradation and release of soil-bound (i.e. non-labile) organoiodine. It is not clear what influence microbes, redox processes, or the nature of the SOM have on long-term I retention in the soil column (Kaplan et al., 2014). Based on a modeling approach for forest sites, Thiry et al. (2022) proposed that, under steady-state conditions, the non-labile I cycle in soil can lead to the storage of about 20% of the total atmospheric deposits, with a mean residence time of 900 years, while labile I is recycled with a mean residence time of 90 years. In that context, the production of volatile I from soil appeared to be a more significant export pathway than drainage of soluble I for most sites.

Both plants and soils are potentially important terrestrial sources of atmospheric methyl iodide (CH_3I) (Sive et al., 2007; Fuge and Johnson, 2015 and references therein). Bacteria seem to play a principal role in volatilization of I from aerated soils and especially in the rhizosphere, although the formation of various volatile organoiodides including CH_3I is also possible through abiotic processes. Knowledge of the rate of I emission from soil remains limited. A few experimental studies using different soil–plant systems reported a possible volatilization loss of 0.01–5% of radioiodine input. A mean release of $0.16 \text{ mg I m}^{-2} \text{ yr}^{-1}$ from a forest soil has also been measured at Duke Forest, USA (Sive et al., 2007). That flux was consistent with other measurements made at two coastal coniferous bog sites in Ireland.

In general, developing a budget including volatile I in soil is complicated by the poor understanding of the spatial and temporal variability in its production, consumption, and diffusion within the soil column. While rainfall transfers large amounts of I with an obvious atmospheric marine source in coastal soils, it is believed that ‘land hopping’ involving volatilization from the terrestrial environment and further re-deposition may greatly influence I inputs to inland soils. In any geographic situation, variation in local edaphic conditions is expected to influence the capacity of soil greatly to retain the atmospheric inputs of I, and finally the spatial variability of I content in soils.

Fig. 1 Total halogen stocks in foliar biomass (mol ha⁻¹), organic layers (kmol ha⁻¹) and mineral soil (kmol ha⁻¹). 1: Montelius et al. (2015), 2: Svensson et al. (2021), 3: Öberg et al. (2005), 4: Epp et al. (2020), 5: Redon et al. (2013), 6: Redon et al. (2013), 7: Johansson et al. (2001), 8: Zlamal et al. (2017), 9: Yuita, (1983), 10: Cortizas et al. (2016), 11: Takeda et al. (2018), 12: Roulier et al. (2019), 13: Bowley et al. (2019), 14: Roulier et al. (2019). Note that these publications include a wide variety of soil types (e.g., Cambisols, Umbrisols, Andosols). Because variables required to calculate the mass of each compartment were published in two studies only, we used these for all other studies as well (reference no. 12: foliar biomass: 5100 kg ha⁻¹; reference no. 4: organic layer: 10.5 cm thickness, 0.7 g cm⁻³ bulk density; mineral soil: 60 cm thickness, 1.3 g cm⁻³ bulk density). The resulting masses were then multiplied by the published total halogen concentrations. The box width reflects the stock size. * Note that the box width of F stocks in mineral soil could not be displayed proportionally: the width is the same as for Cl stocks, but F stocks are 10 times Cl stocks.

Lessons learned from comparison of the soil halogens

In most soils, a large fraction of chlorine, bromine and iodine derives from atmospheric deposits, which is mirrored in their large soil contents in areas close to the oceans, whereas soil fluorine largely depends on concentration in its parent material. When comparing the halogens on the forest floor, fluorine and chlorine have the largest pools (Fig. 1) primarily due to their greater atmospheric deposition, and because SOM halogenation is particularly active in the organic surface layer (Svensson et al., 2021). Mean wet atmospheric deposition of Cl and I in mol ha⁻¹ yr⁻¹ (96–2208 mol ha⁻¹ yr⁻¹) for chlorine (Redon et al., 2013) and 0.06–0.41 mol ha⁻¹ yr⁻¹ for iodine (Roulier et al., 2019) in French forested areas is about 1000–5000 times less for iodine compared with chlorine. This difference is reduced to about 10 times in soil because of the strong biophilic nature of iodine which promotes its association with SOM compared with chlorine. It is likely that SOM tends to be enriched in bromine, chlorine and iodine through similar halogenation processes. Although SOM chlorination is a well-known source of chlorine accumulation in soil and fundamentally affects long-term Cl dynamics (Svensson et al., 2021), a major part of chlorine (Cl⁻ ions) is highly soluble and rapidly leached from soils. The modeled organic Cl cycle in forest soils showed an accumulation of <1% of the annual atmospheric deposition of Cl in the form of organic chlorine (Tanaka and Thiry, 2020), while the stabilization of organically bound atmospheric I input was about 20% (Thiry et al., 2022). Interestingly, the residence time of both organic pools in soil is similar, but the major export pathways are different. Though the estimates of Cl volatilization are large, drainage of Cl would probably be a relatively more significant export pathway than volatilization while volatile I production from soil would represent the major losses for most sites.

The comparison of the fate of the different halogens in soil is constrained by a predominance of halogen-specific studies with different methodologies, whereas a few studies only measured several halogens at the same site (e.g., Suess et al., 2019). Therefore, multi-halogen studies are essential and should include sources, speciation, measurements of soil processes, volatilization and multi-isotope approaches. Previous studies of halogens have revealed differences between soil types, and local variation within sample plots that can be being partly explained by environmental variables. Thus, knowledge on the variation of the stocks and fluxes in soil of different ecosystems are of fundamental importance for future knowledge on halogens biogeochemistry.

Abstract

Microorganisms exhibit a variety of direct and indirect mechanisms that can alter the chemical speciation of metals and metalloids, and their release from minerals and other solid substrates. Such mechanisms are important components of biogeochemical cycles for metal(loid)s, and may be important determinants of microbial metal tolerance or resistance. Those mechanisms that alter metal mobility through, e.g., solubilization or bioprecipitation, are of significance in transformations of environmental pollutants, as well in environmental biotechnologies such as bioleaching, bioremediation and element biorecovery.

Key points

- To survey the main mechanisms by which prokaryotes and fungi interact with and chemically transform metals and metalloids
- To emphasize the importance of metal and mineral transformations in biogeochemical processes and in environmental biotechnology

Introduction

Fungi and prokaryotes from all major taxonomic groups are found in metal-rich habitats such as [mineral ores](#) and leachates, acidic soils, or polluted environments. The survival of these [microorganisms](#) may depend on a number of biochemical, structural, and physiological properties that modify metal [bioavailability](#) and toxicity, which are constitutive to a species and/or have been selected by adaptation.

All microorganisms have essential metabolic and structural requirements for specific metals in metabolism, including potassium (K), sodium (Na), magnesium (Mg), calcium (Ca), manganese (Mn), iron (Fe), copper (Cu), zinc (Zn), cobalt (Co), and nickel (Ni), while some metals, e.g., rubidium (Rb), caesium (Cs), aluminium (Al), cadmium (Cd), silver (Ag), gold (Au), mercury (Hg),

and lead (Pb), and **metalloids**, e.g., arsenic (As) and tellurium (Te), have no apparent essential function. Intense competition for some metals, coupled with low bioavailability, has driven the evolution of tightly regulated mechanisms for metal acquisition. These include highly specialized, metal-specific **membrane transport** systems and metal chelates to scavenge metals effectively from the environment. All metals and metalloids, regardless of their metabolic function, are, however, toxic in excess and can inhibit growth, affect **sporulation** and adhesion, induce morphological changes, and affect biochemical activities. This potential toxicity has necessitated organisms to develop diverse mechanisms of defense. Both genetically-coded mechanisms of resistance and non-specific mechanisms such as oxidation or reduction of the metals to produce less toxic chemical species, or **sorption** and precipitation on cell surfaces and exterior to cells, can protect cells from toxic metals.

The chemical form, or species, of metals and metalloids is also affected by microbial processes other than those related to nutrition and toxicity. Metal speciation is important because different metal species can have widely differing chemical and biological properties, including mobility in the environment and toxicity. Excreted cellular metabolites transform metal compounds by non-specific reactions such as dissolution by protons and organic acids. Some bacteria use metals as electron donors and acceptors during respiration, a process that is a major pathway for the cycling of metals in soils and sediments. Such microbial transformations both mobilize and precipitate metals, leading to alteration and modification of soils and sediments. Many of these processes also have potential for the **bioremediation** of metal-contaminated sites as well as the biorecovery of valuable elements (Lloyd et al., 2008; Gadd, 2010; Johnson, 2014).

Microbially-induced metal transformations

Interactions between **microorganisms** with metals and soil components take many forms: unravelling their complexity is integral to understanding metal speciation in the soil. The relative roles of fungi, archaea and bacteria depend on associated biota (other microorganisms, plants, and animals) as well as on **abiotic factors** such as physicochemical components of the environmental matrix, e.g., pH, water, inorganic and organic ions, molecules, compounds, colloids, and particulates (Sullivan and Gadd, 2019) (Fig. 1).

The ability of microorganisms to affect metal speciation in the soil environment stems from two opposing basic phenomena: mobilization and immobilization, which influence the distribution of metal species between soluble and insoluble phases. **Solubilization** of metals can be achieved by various mechanisms: protonation, chelation, redox and chemical transformations. Metal immobilization can occur by precipitation or crystallization of insoluble organic or **inorganic compounds**, or by **sorption**, uptake, and intracellular sequestration. In addition, redox reactions can mobilize or immobilize metals, depending on the environment, metal and microbial species (Banfield and Nealson, 1997; Lovley, 2000; Hernandez and Newman, 2001; Korenevsky et al., 2002; Gadd, 2010).

Fig. 1 Fungal and bacterial interactions with metals and metalloids in the soil environment. Metal(loid) species lost from the soil environment are indicated by broken arrows. Interactions mediated by **microorganisms** are indicated by solid arrows.

Mobilization

Fungi and bacteria can facilitate the transformation of metals into soluble forms via the dissolution of metal compounds, including oxides, phosphates, [sulfides](#), and more complex [mineral ores](#), or by desorption from exchange sites on, for example, clay minerals, colloids and organic matter. Metal leaching by Fe- and S-oxidizing bacteria is discussed further on. A number of other pathways by which [microbes](#) can leach [metal ions](#) have been proposed.

Acidification

Competition between protons and the metal (in a metal-anion complex) leads to protonation of the anion under conditions of increased acidity, and results in the release of free metal cations. Fungi and bacteria can acidify their environment in a number of ways; for example, proton [efflux](#) via [plasma membrane](#) H^+ -ATPases, maintenance of charge balance, or as a result of respiratory carbon dioxide accumulation.

Complexation by ligands

Microorganisms produce a number of extracellular metabolites that can complex metals in solution, including [polysaccharides](#), pigments, organic acids, and [siderophores](#). Organic acids are important in energy production as intermediates in the tricarboxylic (TCA) cycle and in cellular pH [homeostasis](#). They can correct internal perturbations in charge balance and pH resulting from [nutrient uptake](#) by their ability to produce and consume protons via the formation and removal of carboxylic groups, and by efflux from cells.

Citric and [oxalic acids](#) are the most commonly reported organic acids in soils and are released into the soil by fungal [hyphae](#), [lichens](#) (a symbiotic relationship between a fungus and a photosynthetic [cyanobacterium](#) and/or alga), bacteria, and plant roots and symbiotic mycorrhizas. Organic acids are believed to play an essential role in nutrient acquisition as a result of their [acidification](#) and metal-binding properties. For example, phosphate is released from common soil compounds such as phosphates of calcium, iron, and aluminium ($CaHPO_4$, $Ca_3(PO_4)_2$, $FePO_4 \cdot 4H_2O$, and $AlPO_4$, respectively) either by direct exchange of chemically binding species, or ligands, between phosphate and the [organic anion](#) or by binding of the metal to the anion. Metal complexation depends on metal-to-anion availability, the stability of the particular metal-ligand complex, and pH. Anion concentration (which will depend on the pK_a of the acid) is important, because fully protonated organic acids chelate metals poorly. The affinity depends on the stability constant of the organic acid-metal complex. For example, the efficiency of organic acids to solubilize phosphate from soils often follows the order: citrate > [oxalate](#) > malate > acetate. The [bioavailability](#) of a solubilized metal-ligand complex will depend ultimately on its long-term fate in the environment, including [sorption](#) to components of the soil matrix or potential utilization by biota. Metal citrates can be highly resistant to microbial degradation and this can result in effective leaching of metals from soil. In contrast, metal oxalates may crystallize depending on metal and oxalate concentrations, pH, and the organisms involved (Gadd, 2007; Gadd et al., 2014).

Many soil bacteria, fungi, and lichens are particularly efficient at solubilizing metal phosphates and other metal-bearing compounds, which has been attributed to their ability to produce protons and organic ligands. This can be demonstrated in simple laboratory experiments: if insoluble metal compounds are incorporated into solid growth medium, clear zones may appear around microbial colonies if they are capable of mineral dissolution.

In addition, organic acid production by microbes is an important agent of rock and mineral biodeterioration, playing a role in both biogenic chemical weathering and soil formation. Fungi can also physically weather minerals by etching and fracturing mineral grains during hyphal growth (Burford et al., 2003). Such effects are also evident in the built environment where fungi are the prevalent microbial form causing biodeterioration of rocks, minerals and mineral-based building materials.

Siderophores

Siderophores are the largest class of known compounds that can bind and transport, or shuttle, Fe. They are highly specific Fe(III) ligands with formation constants often greater than 10^{30} . These [low-molecular-weight](#) coordination molecules are excreted by a wide variety of fungi and bacteria to aid Fe assimilation. Although the mechanism could be used to acquire other metals, Fe is the only known essential element for which these specific organic shuttles operate. This is most likely because Fe is needed in larger amounts by cells than other poorly soluble metals, and, given the low solubility-product constant of ferric hydroxide (less than 10^{-38}), the concentration of free Fe is too low to support [microbial growth](#) at pH values where most life exists.

In a typical soil, many different species, including plants, compete for Fe via siderophores. Organisms have most likely evolved mechanisms to ensure that the demand for essential Fe is met through the production of species-specific siderophores, or by attachment to solid Fe-containing minerals (e.g., Fe oxides), to shorten the pathway between the Fe substrate and the site of uptake.

Biomethylation

[Methylation](#) of Hg, As, Se, Sn, Te, and Pb can be mediated by a range of microorganisms, including [clostridia](#), [methanogens](#), and [sulfate-reducing bacteria](#) under [anaerobic conditions](#), and principally fungi under [aerobic conditions](#), such as *Penicillium*,

Cephalosporium, and *Alternaria* spp. as well as a variety of bacteria, including pseudomonads. Methyl groups are enzymatically transferred to the metal, and a given species may transform a number of different metal(loid)s. Methylated metal compounds formed by these processes differ in their solubility, volatility, and toxicity. Volatile methylated species, e.g., dimethyl selenide $((\text{CH}_3)_2\text{Se})$ and dimethyl diselenide $((\text{CH}_3)_2\text{Se}_2)$, can be lost from the soil, reducing potential selenium toxicity to the biota. Methylation can also increase element toxicity; e.g., methylmercury (CH_3Hg^+) produced by bacteria in anaerobic sediments is highly toxic.

Redox reactions

Microorganisms can mobilize or immobilize metals, metalloids, and organometallic compounds by reduction and oxidation processes (Lovley, 2000; Korenevsky et al., 2002; Lloyd et al., 2008; Gadd, 2000, 2010; Johnson and du Plessis, 2015) (Fig. 2). For example, oxidation of metal-complexing dimethylsulfide, dimethylsulfoxide, or thiosulfate increases metal availability if metal sulfates are formed, and the solubilities of Fe and Mn increase upon reduction of Fe(III) to Fe(II) and Mn(IV) to Mn(II). While many microorganisms reduce small amounts of Fe during metabolism, most Fe reduction is carried out by facultative and strictly anaerobic bacteria such as *Shewanella* spp. and *Geobacter* spp. that use Fe(III) for respiration, and there is evidence that reduction of Fe(III) was one of the first forms of microbial respiration. In this process, oxidized forms of metals are used as the final electron acceptor in place of oxygen that is consumed during aerobic respiration. Dissimilatory metal-reducing bacteria respire and thereby reduce oxidized metal species at or near the outer cell membrane. The membrane-bound electron transport system provides energy to cells by cycling electrons through an electrochemical cascade of metalloenzymes, expelling electrons (e^-) and protons (H^+) from the cell. Energy is generated by the flux of H^+ into the cell through specific membrane-bound channels (Fig. 3). Dissimilatory metal-reducing bacteria can use a variety of metal(loid)s with an appropriate redox couple, including Fe(III), Mn(IV), Se(IV, VI), chromium(VI) (Cr(VI)), and uranium(VI) (U(VI)). While Fe(III) and Mn(IV) increase their solubility upon reduction, the solubility of other metals such as U(VI) to U(IV) and Cr(VI) to Cr(III) decreases, resulting in immobilization (see section “Precipitation of metals and minerals,” below). Reduction of Hg(II) to Hg(0) by bacteria and fungi results in diffusion of elemental Hg out of cells, and conferment of Hg resistance on organisms that possess this property since Hg(0) is less toxic than Hg(II).

Dissimilatory metal reduction requires that bacteria access relatively large amounts of insoluble metals. Bacteria can use redox-active organic compounds to shuttle electrons between cells and the metal being respired under anaerobic conditions. Many quinoid compounds, common components of humic substances, can function as electron shuttles. These compounds move electrons from the cell membrane to the target metal, such as Fe(III) contained in ferric oxides. The shuttle molecule regenerates when the metal is reduced and the cycle continues (Fig. 4). While the use of electron shuttle mechanisms appears to be widespread among bacteria, the impact and ecologic significance of the process in natural subsurface environments is still not fully understood.

In the absence of processes that mix water columns, sediments, and soils, redox potentials tend to decrease with depth, reflecting a change in the dominant electron acceptors from O_2 to NO_3^- , Mn(IV), Fe(III), and SO_4^{2-} . The interplay between microbial and abiotic metal reduction forms characteristic element profiles (Fig. 5). *Shewanella*, *Geobacter*, and *Desulfovibrio* spp. were among the first bacteria to be intensively studied for their metal-reducing capability, and species continue to be added to the group of bacteria

with this capability. Molecular studies reveal that many as yet uncultured species exist in the subsurface which can also contribute, and improved culturing methods are likely to show novel dissimilatory metal reducers among these organisms. The poorly crystalline iron fraction is generally considered to be the 'reactive' fraction for these bacteria; however, iron in some clay minerals and crystalline Fe oxides could also be available for reduction.

Immobilization

There are a number of processes whereby microorganisms and **microbial biomass** can immobilize metals in the soil environment. Although immobilization reduces the external free metal activity, it may also shift the equilibrium to release more metal into the soil solution.

Biosorption

The strong interaction of metals with cell surfaces stems from cell wall characteristics, including component pigments and **polysaccharides**, and extracellular polymeric substances (EPS). Bacterial cells depend on the diffusion or transport of nutrients for survival, and their small size, shape, and characteristic **membrane structures** have evolved to maximize their interaction with nutrient solutes (Beveridge and Doyle, 1989; McLean et al., 2002; Korenevsky et al., 2002). There is remarkable similarity in the general format of bacterial wall structure, which falls into two broad classes based on reaction with the Gram stain, which utilizes **crystal violet**. Gram-positive walls consist of a thick matrix of **peptidoglycan** and secondary polymers, which provide structural support and give the cell its shape and form (Fig. 6). The phosphate and **carboxyl groups** within the wall fabric and exposed at the surface confer pH-dependent negative charge to the cell in the types of environments where **microbes** generally exist. The point of zero charge (PZC), or pH where positive charge equals negative charge, is approximately pH 2–3 for bacterial cell walls. This charge provides the basis for metal **sorption**. At pH values above the PZC, the net charge on the cell wall is negative, which facilitates sorption of positively charged metal species. Gram-negative cells are also negatively charged, although structurally more complex. In this case, a thin layer of peptidoglycan floats in a gel-like periplasm, sandwiched between the **plasma membrane** and the outer membrane (Fig. 6). The outer membrane has characteristic surface **lipopolysaccharides** (LPS) containing ionizable phosphoryl, carboxyl, hydroxyl, and amine groups; the phosphoryl groups are the most reactive to metals. In addition to these basic structures, surface capsules, sheaths, EPS and S-layers provide additional sites for metal interaction and the heterogeneous nucleation of minerals (Beveridge and Doyle, 1989).

Fungal cell walls are predominantly composed of polysaccharides (80–90%) with **glycoproteins** and some lipids. The polysaccharide component includes microcrystalline fibrils of β -linked polysaccharides (chitin, chitosan, and β -glucans) that are responsible for wall strength and rigidity. As for bacteria, the chemical properties of the functional groups associated with fungal walls, including carboxyl, amine, hydroxyl, phosphoryl, and sulfhydryl groups, provide the basis for the sorption of metals to cell walls. In addition, pigments such as **melanin** contribute to rigidity and have significant metal-binding properties, preventing metal entry into melanized structures and contributing to survival in the presence of potentially toxic metals as well as other stress factors like desiccation and ultraviolet (UV) irradiation (Gadd, 2007; Fomina and Gadd, 2014).

Precipitation of metals and minerals

Partitioning in the cellular environment

Metals are found in all parts of bacterial and fungal cells: in the **cytoplasm**, the cell wall, or sorbed to cell surfaces and extracellular materials (Beveridge and Doyle, 1989; Gadd, 2007, 2010; French et al., 2013). At sufficient concentrations, metal precipitates can

Fig. 6 Cross-sectional view showing the basic cell wall structures characteristic for Gram-positive (left) and Gram-negative (right) bacteria. LPS, lipopolysaccharide.

develop or nucleate on or within cells, or in the immediate extracellular environment (demonstrated for a bacterial cell in Fig. 7). In addition to immobilizing metals, this also reduces the external free metal activity and may shift the equilibrium to release more soluble metal species to the soil solution. Precipitation and crystallization can restrict metal leaching and **bioavailability**, and can also release nutrients such as **sulfate** and phosphate.

The formation of extracellular and sorbed precipitates depends on the chemical composition of the extracellular environment and can be mediated or influenced by cellular processes (French et al., 2013). The precipitates can be copious and may completely entomb the cells, effectively entombing them (Fig. 8).

Environmental anions, such as hydroxyl (OH^-), sulfate (SO_4^{2-}), sulfide (S^{2-}), phosphate (PO_4^{3-}), carbonate (CO_3^{2-}) and oxalate ($\text{C}_2\text{O}_4^{2-}$), provide counterions for mineral hydroxides, sulfate and **sulfides**, phosphates, carbonates, and **oxalates** (Gadd, 2010). It is likely that cellular metabolism and excretion of such anions also contributes to the formation of these minerals, e.g., sulfide, oxalate, as observed for the formation of framboidal pyrite (FeS_2) (Fig. 9).

Fig. 7 Possible locations of metal precipitates and minerals associated with a bacterial cell: (A) biogenic precipitates within the cell **cytoplasm**; (B) metal precipitates formed by nucleation in the cell wall, e.g., periplasmic; (C) mineral **nanocrystals** formed independently of cell activities and subsequently sorbed to the cell wall; (D) minerals formed outside cells due to the influence of cellular activities.

Fig. 10 Transmission electron micrograph of a thin section showing abiotically precipitated goethite nanocrystals sorbed to the cell wall of *Shewanella putrefaciens*. Scale bar 150 nm.

Metal oxide and hydroxide minerals formed by abiotic reactions can also attach to cells, and it can be difficult to distinguish these phenomena (Fig. 10). This is, however, another important mechanism by which cells concentrate metals as well as by anions released through solubilization of, for example, mineral phosphates.

Inside cells, metals can be incorporated into cellular constituents. Excess or toxic metals may be effluxed, form intracellular precipitates, bind to metal-complexing molecules, and, in eukaryotes, partition into vacuoles. The formation of internal precipitates may result from a change in metal oxidation state, which does not require an active cell; for example, gold is highly toxic to cells, yet intracellular precipitates of elemental gold form in bacteria after cells are killed. The formation of oriented chains of magnetite (Fe_3O_4) crystals by magnetotactic bacteria, found in sediments and hydric soils, is a unique example of directed, intracellular biomineralization in a prokaryote. In this case, the formation of magnetite may enable the bacteria to orient in the Earth's magnetic field, although other explanations have been proposed.

Fig. 11 Copper oxalate precipitated by *Beauveria caledonica*. The spherical crystals are associated with extracellular polymeric substances (EPS) produced by the filamentous hyphae and hyphal strands. Scale bar 200 μm (scanning electron micrograph produced by Marina Fomina).

Oxalates

Calcium oxalate is the most common form of oxalate associated with soils and leaf litter, occurring as dihydrate (weddellite) or the more stable monohydrate (whewellite). Calcium oxalate crystals are commonly associated with free-living, pathogenic, and plant-symbiotic fungi and are formed by the precipitation of soluble calcium as the oxalate. Fungal-derived calcium oxalate can exhibit a variety of crystalline forms (tetragonal, bipyramidal, plate-like, rhombohedral, or needles), which often associate with the outer surfaces of hyphae. The formation of calcium oxalate by fungi has an important influence on biological and geochemical processes in soils, acting as a reservoir for calcium in the ecosystem, and also influencing phosphate availability (Burford et al., 2003; Gadd, 2007; Gadd et al., 2014).

Fungi can also produce other metal oxalates with a variety of different metals and metal-bearing minerals, e.g., Cd, Co, Cu, Mn, Sr, and Zn (Fig. 11). The formation of metal oxalates may provide a mechanism whereby fungi can tolerate environments containing potentially high concentrations of toxic metals. A similar mechanism occurs in lichens growing on copper sulfide-bearing rocks, where precipitation of copper oxalate occurs within the thallus (see Gadd et al., 2014).

Carbonates

In many arid and semiarid regions, calcareous soils and near-surface limestones (calcretes) are often secondarily cemented with calcite (CaCO_3). This phenomenon has been partly attributed to physicochemical processes, although the abundance of calcified fungal filaments in weathered profiles of chalky limestone and Quaternary calcretes indicates fungal activity (Verrecchia, 2000). Calcite precipitation on fungal hyphae has been observed with the ectomycorrhizal fungus *Pisolithus tinctorius* in calcareous soil, as well as many other fungal species.

It has been proposed that calcite forms indirectly through fungal excretion of oxalic acid and precipitation of calcium oxalate, which results in dissolution of the internal pore walls of the limestone matrix. This enriches the matrix solution in free carbonate ions. During passage of the solution through the pore walls, calcium carbonate recrystallizes as a result of a decrease in CO_2 , hardening the limestone. Calcite crystals act as sites of further secondary calcite precipitation when the hyphae decompose. Through these processes, fungal activity is important in lithification (hardening), alteration, and diagenesis of subsurface limestone formations (Verrecchia, 2000).

Biomined carbonate precipitates are also found in association with bacterial biofilms. One striking example of microbial carbonate precipitation is the towering microbialites at Lake Van (Turkey), formed by thick biofilms of cyanobacteria (*Pleurocapsa* spp.) that colonize crusts of inorganic calcite precipitated in the alkaline soda lake water. Groundwater forced up and through the carbonate matrix raises the towers of aragonite and calcite to heights up to 40 m.

Redox reactions

Bacterial and fungal oxidation

The range of bacterial species with the capability to oxidize Fe and Mn spans sedimentary and soil environments. For bacteria to use Fe(II) specifically for growth, however, they must recover the energy produced in the oxidative process. Demonstration of a respiration-linked, energy-yielding reaction is particularly difficult for iron due to its rapid chemical oxidation at neutral pH and in the presence of atmospheric O_2 . It has been more readily shown for bacteria that grow at low pH and/or low O_2 , conditions that drastically slow chemical oxidation of Fe(II). Bacterial Fe oxidation is probably ubiquitous in environments with sufficient Fe^{2+} and conditions to support the growth of bacteria that can live by oxidative respiration of reduced metal species. Specific environments include drainage waters and tailing piles in mined areas, pyritic and hydric soils (bogs and sediments), drain pipes and irrigation ditches, and plant rhizosphere zones.

Iron-oxidizers found in acidic soil environments are acidophilic chemolithotrophs, organisms that use inorganic sources of chemical energy, such as *Acidithiobacillus ferrooxidans*, which is important for its role in generating acid mine drainage. Facultative chemolithotrophic microaerophiles such as *Leptothrix ochracea*, *Sphaerotilus natans*, and *Gallionella ferruginea* are common in mildly acidic to neutral environments, and accumulate abundant Fe hydroxide precipitates on their filaments or stalk structures that can age to more crystalline minerals.

After Fe, Mn is the second most abundant transition metal in the Earth's crust and is actively cycled in the same environments as Fe. Manganese oxidation is carried out by many of the organisms that are implicated in Fe oxidation, including *Bacillus*, *Pseudomonas*, and *Leptothrix* spp. In contrast to Fe^{2+} , substantial chemical oxidation of Mn^{2+} does not occur below pH 8, and solutions containing Mn^{2+} can be stable for weeks. This fact has allowed bacterial Mn oxidation to be identified more readily than its Fe counterpart.

It is not yet clear why cells carry out metal oxidation if not for gaining energy. Oxidation may enable the cell to rid itself of toxic intracellular concentrations of the metal, or the precipitates that coat the bacterial surface subsequent to oxidation may protect the cells from external stresses including predation by other microbes. Protection from UV radiation would have been especially crucial during the early evolution of life on Earth.

Fungi can also oxidize metals in their environment. Desert varnish is an oxidized metal layer (patina) a few millimeters thick found on rocks and in soils of arid and semiarid regions, and is commonly believed to involve fungal and bacterial processes. *Lichenothelia* (a fungus) can oxidize manganese and iron from metal-bearing minerals such as siderite (FeCO_3) and rhodochrosite (MnCO_3), and metals from rainfall or windblown dust. Several other fungal species can also promote Mn(II) oxidation to Mn(IV) O_2 through indirect mechanisms, such as interaction with a metabolite or structural component, and/or direct enzymic mechanisms mediated by, e.g., multicopper oxidases.

Dissimilatory metal-reduction by bacteria

When dissimilatory metal-reducing bacteria utilize relatively soluble metals such as Cr(VI) and U(VI) as electron acceptors, less-soluble Cr(III) and U(IV) species may result. Once reduced, soluble metals sorb to the cells and to extracellular polymers or partition to the bulk extracellular solution, where new minerals can form from the metals and suitable counterions. Post-reduction partitioning of metals depends on the element. For example, U(IV) accumulates as fine precipitates in the periplasm of Gram-negative metal reducers (Fig. 12). The Fe^{2+} and Mn^{2+} , generated by dissimilatory reduction, can form copious extracellular precipitates and nodules. The fate of the reduced metal depends on the environment, and it is feasible that a metal such as Fe, together with any associated redox-active metals, could be cycled hundreds of times between reducing and oxidizing zones before being incorporated into refractory minerals (Fig. 13).

Fungi and other microorganisms also precipitate reduced forms of metal species, e.g.: Ag(I) to Ag(0); selenate (Se(VI)) and selenite (Se(IV)) to Se(0); and tellurite (Te(IV)) to Te(0), by a variety of mechanisms (Gadd, 2007, 2010; Nanchaiaiah et al., 2016).

Fig. 12 Transmission electron micrograph of a thin section showing uranium precipitates formed in the periplasmic space of *Geobacter metallireducens* cells during dissimilatory reduction of U(VI). No metal stains were used, so that the contrast in the image is from the uranium precipitates only. Scale bar 150 nm.

Fig. 13 Cycling of Fe between soluble and insoluble mineral, oxidized and reduced forms mediated by **microorganisms** in soils and sediments. Although by quantity Fe is the major element to undergo redox transformations, other metals, e.g., Mn, can be cycled by the same processes and associate with the precipitating minerals.

Biotechnological applications of microbial metal transformations

Ore leaching

Metals in ores that are not worth recovering by smelting can sometimes be effectively leached by bacteria and fungi. Important species of bacteria in such bioleaching processes are Fe and S **oxidizers** such as *A. ferrooxidans*, *Acidithiobacillus thiooxidans*, and *Leptospirillum ferrooxidans*. Their activities solubilize Fe and S contained in metal **sulfides**, with the concomitant release of associated metals such as Cu and Zn (Johnson, 2014). Large amounts of Fe^{2+} and **sulfuric acid** are generated in the process. It is most commonly accepted that the bacteria catalyze the oxidation of Fe^{2+} to regenerate Fe^{3+} , but do not directly attack the mineral:

where Eq. (1) gives the reaction for bacteria, and Eq. (2) is the abiotic reaction. There is, however, increasing evidence that *A. ferrooxidans* may directly enhance dissolution of metal sulfides via an enzymatic mechanism. Approximately 90 mol Fe^{2+} is oxidized to assimilate 1 mol C, which explains the tremendous amount of acidity—‘acid mine drainage’—that is generated. Industry can take advantage of the acidic leachate by recirculating it through the **ore body** to dissolve and harvest more metal. Here, the acidic leachate is recirculated through the ore body to solubilize more metal, and the soluble metals are then separated by sedimentation, solvents, or **electrodialysis**. When uncontrolled, such as at poorly managed or abandoned mining sites, the same process can have disastrous environmental consequences.

Extracellular ligands produced by fungi, including *Aspergillus* and *Penicillium* spp., have also been used to leach metals such as Zn, Cu, Ni, and Co from a variety of solid materials, including low-grade **mineral ore**, **solid waste**, and **electronic scrap** materials.

Bioremediation

Toxic metals in natural, industrial, and agricultural soils may be a risk to biota at all **trophic levels** if they exist at potentially toxic levels and are, or become, bioavailable. Some of the processes outlined above have potential for application to treat contaminated land. **Solubilization** processes provide a route for removal of metals from soil matrices, whereas immobilization processes enable metals to be transformed to insoluble chemically inert forms (Gadd, 2000, 2001). Although some processes can be used in situ (e.g., leaching using S-oxidizing bacteria), many are probably most suitable for ex situ use in **bioreactors**, where the mobilized or immobilized metal can be separated from soil components. The industrial development and operation of large-scale bioreactors containing sulfate-reducing bacteria for metal decontamination of effluents and process streams is now well known. Living or dead fungal and bacterial **biomass** and metabolites have been used to remove metals and **metalloids** from solution by biosorption or chelation, but sustained commercial application has not been achieved (Fomina and Gadd, 2014).

There has been interest in the ability of some mycorrhizal fungal **symbionts** to improve plant metal tolerance and increase metal translocation to the aboveground parts of plants. Such associations could be used to enhance the **phytoextraction** capabilities of plants grown for removing toxic metals from soil by accumulation in their shoots. Amelioration of metal **phytotoxicity** by **mycorrhizal fungi** has been widely demonstrated, particularly when inoculated with mycorrhizas isolated from metalliferous or **acid soils** (Gadd, 2007).

The increased attention to [microbial activities](#) in anaerobic, subsurface environments in the past few years has opened up new possibilities for the [bioremediation](#) of metal contaminants (Lovley, 2000). Metal(loid)s that form insoluble precipitates when reduced may be of particular interest for in situ treatment, such as Se(0), Cr(III), Tc(IV), and U(IV). Natural processes in subsurface soil may immobilize contaminants otherwise predicted to leach. Thorough knowledge and monitoring of the system are essential for such treatment schemes, because reoxidation can result in mobilization.

Biorecovery

There is growing concern about the security of supply of metal and mineral resources, particularly for those metals important in new digital technologies, electronics, and sustainable energy generation because of depletion of natural resources and inadequate reclamation and recycling. Many microbial metal and mineral transformations are relevant to biorecovery of critical metals, and bioprocessing is viewed as a useful contributor to solving this problem (Liang and Gadd, 2017). Reductive dissolution of oxidized ores can be used for recovery of cobalt and nickel, as well as other metals, in a more environmentally-friendly and cost-effective approach in comparison to traditional biomining (Johnson and du Plessis, 2015; Smith et al., 2017). Other potential approaches with apparent environmental benefits include biorecovery through bioprecipitation from solution using microbial metabolites or ligands released into solution through microbial activity. These include phosphate, liberated from organic or inorganic sources by phosphate-solubilizing organisms, fungal oxalate excretion, and microbially-induced carbonate precipitation (MICP). All such mechanisms have been examined for metals such as cobalt and nickel (Li and Gadd, 2017; Liang and Gadd, 2017; Yang et al., 2020), as well as biorecovery of rare earth elements (REE), e.g., cerium (Ce), lanthanum (La), neodymium (Nd), praseodymium (Pr), from leachates or monazite resources (Corbett et al., 2017; Kang et al., 2020), often exhibiting high efficiency in laboratory or pilot-scale demonstrations.

Summary

Dissolution, precipitation, oxidation, and reduction processes are vital to metal cycling in aerobic and anaerobic surface and subsurface environments. As active agents in cycling, bacteria, archaea and fungi are fundamental biotic components of natural [biogeochemical cycles](#) for metals and [metalloids](#). Some important processes catalyzed by [microorganisms](#) also have important applications in environmental [biotechnology](#) in the areas of ore leaching, [bioremediation](#) and element biorecovery.

Abstract

The chemistry of radioactive isotopes in soil does not differ from that of their stable isotopes. There are however three important differences: radioisotopes are often present in trace amounts; isotopes may change chemical and physical form when they decay; and adverse effects on biological organisms may occur without physical contact or absorption due to ionizing radiation. Case studies are given for the most environmentally relevant isotopes.

Key points

- Concepts, definitions and units of radioactivity
- Similarities and differences between radionuclides and various pollutants and nutrients
- Effects of soil on mobility of radionuclides and exposure of living organisms to radiation
- Examples of most relevant radionuclides in soil

Introduction

The objective of this chapter is to give an overview of the role of soil in the bioavailability of radionuclides and the exposure of living organisms to radioactivity. The essential concepts and units are presented, and the dynamics of radionuclides compared to stable elements, whether they are nutrients or potentially toxic. More detail can be found in standard texts on nuclear physics and radioprotection and in the information sheets produced for the general public by the International Atomic Energy Authority (IAEA), UN (UNSCEAR, 2000) and many national authorities (for example Desmet et al., 1990; Keith-Roach and Livens, 2002; Tykva and Berg, 2004). Detailed reviews of the dynamics of radionuclides are given in the three volumes of the books by Coughtrey and Thorne (Coughtrey et al., 1983; Coughtrey and Thorne, 1983a, 1983b).

Definitions

Radionuclides or radioisotopes are isotopes with unstable nuclei that lose energy by decaying and releasing ionizing radiation; decay may result in a radioactive or a stable isotope that may be the same element or a different element with different chemical properties. Natural radionuclides may be primordial, namely present at the origin of the Earth and so long-lived that they are still present, (Ishii et al., 2004) or secondary, namely formed as part of the decay chain of primordial isotopes, or (iii) formed by cosmic radiation, as in the case of ^{14}C . There are also man-made radionuclides produced during nuclear energy production, military activities and for therapeutic reasons. The three classes of radioactive decay that are relevant to environmental science, and the ionizing radiations produced, have different physical properties.

- Gamma (γ) radiation is electromagnetic radiation released from the nucleus of atoms. In common with X-rays, produced by electronic transitions, outside the nucleus, this radiation penetrates matter, losing energy, with the potential to harm living organisms. It is attenuated by physical barriers, but not completely stopped.
- Beta (β) radiation is formed by electrons (e^-) or positrons (e^+) created within the nucleus by the transformation of a neutron to a proton and an electron, or of a proton to a neutron and a positron. In both cases the number of protons in the nucleus changes and so the radioactive decay results in a chemical change. The energy of β radiation depends on the decaying element. Radiation is referred to as hard or soft; hard radiation is energetic, energizing radiation such as that emitted by ^{32}P , and soft radiation is weakly ionizing such as ^{14}C . This radiation can be completely stopped by a physical barrier. The thickness of the barrier required to stop this radiation depends on both the energy of the radiation and the nature of the barrier.
- Alpha (α) radiation consists of helium nuclei, known as alpha particles, with an atomic mass of 4 and a charge of +2. After emission of alpha particles, the nucleus changes in both atomic mass and atomic number resulting in a chemical change. These particles interact strongly with matter, losing energy, which makes them easy to stop with physical barriers, but very dangerous to living organisms.

Radioactive decay is stochastic, thus the probability of a radioactive nucleus decaying is random, and described by a constant denoted λ , which is inversely related to the half-life of the radioisotope. Decay rate, or activity, A , which can be expressed mathematically as the rate of decrease in the number of nuclei present, depends on the number of radioactive nuclei present at any time t , N_t , thus.

$$\text{Rate of decay} = A = -dN/dt = \lambda N_t \quad (1)$$

The half-life, $\tau_{1/2}$, is defined as the time for the number of nuclei initially present, N_0 , to decrease by decay to half that number. It is inversely related to λ , as seen by rearranging equation 1, and integrating.

$$\ln 2 = \lambda \tau_{1/2} \quad (2)$$

The units of radioactivity are the Becquerel (Bq), defined as one disintegration per second. The older, non-SI unit is also still used, the Curie (1 Ci = 3.7×10^{10} Bq). Half-life should be expressed in SI units, namely seconds, but is often converted to years and multiples thereof. The biological danger associated with radioactivity depends not only on the radioactivity, but also on the energy transferred, and this is denoted by the absorbed dose, Gray (Gy) defined as one Joule transferred to a material with respect to its mass (J kg^{-1}). The older, non-SI unit is also used, the rad = 0.01 Gy. Finally, since the nature of the radioactivity also influences the danger associated with exposure to radioactivity, a quality factor, Q , is also used to define the effective dose, or Sievert (Sv). The values of Q are 1 for β , γ and X-ray radiations, and 10 and 20, respectively for proton, and alpha radiation respectively. The same quality factors are used to derive the effective dose in rem (roentgen equivalent man) from the absorbed dose in rem.

Radionuclide dynamics: Similarities and particularities

Although in many respects radionuclide dynamics are not different from those of other elements of interest in soils and the environment, some points that merit special attention are summarized below and will be treated in greater detail in the text.

- Environmentally relevant radionuclides may not be the focus of interest as stable isotopes. The most studied elements in soil and environmental sciences are nutrients or potentially toxic. Radionuclides of environmental interest may have no or little known biological role, they may also be present in negligible amounts in the environment. Examples of elements that are predominantly studied as radionuclides include artificial isotopes such as neptunium and technetium, but also elements present in nuclear waste or released from nuclear weapons testing or related to nuclear power production, including cesium, strontium and chlorine. A few exceptions are studied both as radionuclides and stable elements, such as nickel and selenium.
- The chemistry of radionuclides and stable isotopes of the same elements is largely similar. The chemistry of an element is determined by its position in the Mendeleev Periodic Table, and thus its atomic number. Thus to a large extent all isotopes of an element have identical chemistry, regardless of atomic mass. Nevertheless covalent bond strength varies with the mass of atoms and so the strength of covalent bonds and the rates of reactions involving these bonds differ between isotopes, leading to an "isotope effect."
- Concentration effect. Another feature of the chemistry of radionuclides is that they are generally present in tiny amounts and their environmental chemistry may be concentration dependent. An important example of an element where the concentration effect is relevant is radiocesium. This element will be considered later, given its presence in the environment due to atmospheric fallout and accidental releases.
- The isotope ratios of light elements, notably C and N, and more recently heavier elements, arise from either radioactive decay, or from small isotopic discrimination repeated numerous times. These ratios are used either to date material or to study food web ecology. They may also provide information on the source of an element in the environment. In radioecology the isotopic ratio is a particularly useful tool to establish the origin of contamination.
- Decay. Radioactive decay is a stochastic process, and thus completely independent of chemical and physical conditions. This is an important contrast with organic contaminants.

- Change of state. Radioactive decay often leads to a change in the element and thus its chemistry. This may include a change in physical state. The best known example of this is for radon. Radon is formed in the decay chain of uranium and radium. All its isotopes are radioactive. Radon is a gas, but all its progeny (or daughters) are nongaseous. Therefore, once radon has been inhaled, any radon not almost immediately exhaled will remain in the lungs and will decay to give elements that are precipitated, thereby increasing the biological residence period.
- External and internal exposure. A major difference between radioactive isotopes and other potentially toxic species is the risk associated with external exposure to radiation. Some radionuclides, including the actinide elements, may also have chemical toxicity. Radiation may be harmful with no direct contact, ingestion or inhalation, between the isotope and living organisms. The dangers associated with internal exposure are increased because exposure time depends on the residence time in the living organism. A biological or effective half-life, the time required for half the isotope or the radioactivity to be eliminated, is thus defined.
- Soil as source, regulator and shield. The functions of source and shield of soil for radionuclides are similar to those for nutrients or other pollutants. However the shield function is related to the risk of external exposure and thus particular to radionuclides, both natural or introduced by human activity.

The roles of soil in the bioavailability of radionuclides and the exposure of living organisms to radioactivity

Fig. 1 is a schematic representation of the sources of external and internal exposure to radiation. Data are approximate, as exposure varies according to many factors including place of residence, building regulations to limit radon accumulation, occupation, medical procedures, and diet. Man-made exposure is less than that of natural exposure, and even food intake is largely due to natural radioisotopes, for example foods high in potassium due to K-40. Soil may be a source of radionuclides and associated radioactivity. This is the case for natural, primordial or secondary radionuclides, of geological origin. Soil acts as a sink for many radionuclides of anthropogenic origin, in common with many pollutants. As both a source and sink, soil regulates the mobility and biological exposure to radioactive elements. The major sources of man-made radionuclides in the terrestrial environment are from accidental releases, the most notorious being the accidents at the Chernobyl and Fukushima nuclear power plants in 1986 and 2011, respectively. Other, often legal and tolerated, releases have occurred around nuclear power plants. The disposal of radioactive waste is also a potential source of release, probably released into the geosphere with the potential for slow mobility toward the pedosphere. Although radioactive sources are used for medical purposes, these tend to be short-lived. Nuclear weapons testing began after the Second World War and caused atmospheric fallout of radionuclides, the most studied has been ^{137}Cs , which peaked in the early 1960s. Cesium-137 is widely used as a tracer of soil erosion because of the relatively homogenous deposition of fall-out containing this isotope in the Northern hemisphere (Zapata, 2003). The multidisciplinary scientific field of radioecology developed from increasing concern about the impact of radionuclides in the environment, and soil science figures prominently within this field. An illustration of this research focus was the foundation of the Journal of Environmental Radioactivity in 1984. Radioecology is a discipline that has experienced marked fluctuations with peaks in activity following the major accidents at Chernobyl and Fukushima. Although exposure to ionizing radiation must be limited to protect human and animal health, it should be remembered that, except in highly contaminated areas, the radiation exposure from contaminated soil and food is very small compared to

Fig. 1 Relative sources of exposure to ionizing radiation.

that from natural and medical sources. Large variations in terrestrial (including radon) radiation exist, with “high background radiation” areas often associated with black sand containing monazite.

In common with other pollutant substances, the interactions between radionuclides and soil determine their mobility and hence bioavailability. A major feature of these interactions is adsorption, which is often described by the distribution coefficient, K_d , defined as the ratio of content in the adsorbed phase and concentration in solution. The principles underlying the adsorption and desorption of radionuclides are no different from those for non-radioactive pollutants or nutrient elements. When sorption is dominated by electrostatic interactions, there is little distinction between radioactive and stable isotopes of a given element. However, the experimental measurement of adsorption and its sensitivity to various parameters is complicated by the effects of concentration. Environmental concentrations of a radioisotope may differ by orders of magnitude from convenient concentrations for laboratory experiments; this is particularly well documented for radiocesium. Isotopic discrimination is generally assumed to be negligible at the soil solution–biological membrane interface and for transport within living organisms. Nevertheless, the repetition of reactions with a small discrimination leads to isotopic signatures or isotopic fingerprints as observed and interpreted for stable isotopes. Isotopic discrimination is of greater importance for reactions involving covalent bonds, often involving catalytic reactions.

Transfer from soil to the human food chain

Soil–plant transfer is an important step in the contamination of the human food chain. The bioavailability of radionuclides is often described using the soil–plant transfer factor, FT . Although contaminated food and water usually make minor contributions to the exposure of humans to radiation (Fig. 1), protecting the food chain is essential following a serious contamination. In the short term, immediately after an accident, the only solution is to monitor and remove contaminated food from the market, or ban removal of plants and animals from the environment for consumption. Such restrictions were imposed on fishing, hunting and mushroom gathering after the accidents at Chernobyl and Fukushima. In the longer term soil amendments, land-use changes from food crops to fiber or construction-material crops may be recommended. Clay and even silver thiourea ($AgTU$) were tested as amendments to reduce radiocesium uptake, particularly on extensive grazing land, but were usually found not to be cost-effective, or with serious disadvantages. Soils may be fertilized, for example with potassium additions, which may limit the uptake of cesium. The discrimination between radionuclides and other elements is often studied in the context of soil-to-plant transfer. This is a feature of all contaminant availability, more usually referred to as competition, often in the context of pollution. Some radionuclides have no biological role and the elements may be present only in trace amounts in the environment. For example, cesium has similar chemistry to potassium, and strontium to calcium.

Soil ingestion is a significant mode of transfer to the human food chain. Considerable amounts of soil may be ingested by grazing animals, particularly sheep when grass is short. Soil may adhere to vegetation after splash-back and thus be consumed if food is not washed. This mode of entry into the food chain exists for other contaminants, but is most important when the contaminant has been deposited on the soil surface, and is sparingly mobile because it is strongly adsorbed. Inhalation of contaminated soil is another mechanism for contamination, particularly for agricultural workers. Cesium is an example of an element where soil ingestion plays an important role in radioecology.

An important feature of the dynamics of radioisotopes in soil, compared with other potentially harmful substances, is the barrier effect of soil. As described above, radiation may be attenuated or completely stopped by material. There is little risk of external exposure to α -emitters that are stopped by less than 1 mm of a dense material such as soil. For soil contaminated by a β - or γ -emitter, the addition of a layer of soil above them may be an effective solution to limit external exposure to radiation, however the effect on bioavailability depends on many factors.

Remediation of contaminated soils

Various remediation measures have been proposed to limit human exposure to radiation from radiocesium and its the entry into the human food chain. In extreme situations near accident sites, the only feasible solution is to create exclusion zones where access is strictly limited and monitored. Soil may be planted to minimize erosion and contamination of surface and ground water. Land is not used for food or crop production and measures are taken to limit the risk of wild-fires that would cause the release of contaminants into the atmosphere. In less extreme situations, soil may be covered with uncontaminated soil to limit external radiation, and wind erosion. But this is unlikely to reduce plant uptake because of root distribution at depth. Soil fertilization or amendments may reduce soil-to-plant transfer. When agriculture is extensive, as for sheep grazing on upland soils, amendments are unlikely to be cost effective. The solution used is to transfer animals to uncontaminated pasture before slaughter, thus reducing animal contamination to acceptable levels. The application of silver thiourea was proposed to complex radiocesium and thus immobilize it. However this solution was not only expensive, but carried the risk of excessive consumption of potentially toxic silver and thiourea by animals. In many cases, as for non-radioactive contaminants, a cost-effective solution is to use land for non-food crops, but a full safety analysis would include the risk of external exposure from radioactivity in the finished fiber or building material. Common approaches to safe use of contaminated land include the choice of crops that do not accumulate the elements, sometimes due to rooting distribution, and the use of amendments or fertilizers. Potassium fertilization has been used as a remediation measure in Cs-contaminated soils, but the overall effect may be complicated by potentially conflicting biological and chemical effects.

Soil microbiological activity

Radioactivity commonly found in the environment is not thought to have adverse effects on soil microbiological activity. To illustrate this the doses used to sterilize soil or medical equipment may be compared to environmental levels of radioactivity. Sterilization uses radiation of several tens of kGy, typically up to 40 kGy, whereas annual doses from all sources are of the order of mSv, and even in the exclusion area around Chernobyl a day visit for a tourist (avoiding the most dangerous areas) would only result in a dose of the order of μSv , equivalent to about 10 mSv year^{-1} . Another example is that the maximum doses recorded after the accident at Fukushima in 2011 were 400 mSv h^{-1} , equivalent to $3.5 \text{ kSv year}^{-1}$. These figures can be compared to 2 Sv for a session of radiotherapy.

The dynamics of some radionuclides, however, may be sensitive to soil microbial activity. Some radionuclides may be bioaccumulated in microorganisms, including adsorption on biological membranes. Obviously this depends on their adsorption properties and bioavailability. These effects are reviewed by (Lloyd, 2003). Important carrier phases that are sensitive to microbial activity include iron and manganese oxides. Other effects of microbial activity are indirect, and related to the chemical and mineralogical effects of microbial activity, including pH changes, and weathering of soil minerals thereby changing adsorption properties. These effects have not been widely studied. One well known example is the weathering of mica-like minerals to yield frayed-edge sites that have a strong affinity for cesium. In addition, many radionuclides are sensitive to the redox changes that may be caused by microbial activity. These radionuclides include both nonmetals, such as iodine, selenium and technetium, and metals, in particular the actinides and lanthanides, thus many artificial isotopes and the isotopes created in the decay chain of uranium and radon. In many cases the adsorption, and thus the mobility, of the elements differ markedly as a function of their oxidation state. For example, selenium and technetium are sparingly adsorbed by soil minerals and are mobile in soil in their oxidized state (SeO_3^{2-} , SeO_4^{2-} and TcO_4^-). Both abiotic and microbially induced biotic reduction of these species yield less mobile and precipitated species (elementary Se, selenides, $\text{TeO}_2 \cdot 2\text{H}_2\text{O}$ and insoluble sulfides of Tc(IV)). Bacterial respiration has been reviewed with emphasis on Se and Tc by Stolz and Oremland (1999) and Lloyd et al. (1998, 2000). Selenium has also been reported to undergo transformations by bacteria and fungi to yield volatile methylated compounds. Similar reactions are known for iodine, but have not yet been conclusively demonstrated for Tc.

Case study: Cesium

Cesium is an alkali metal (Group 1 of the Periodic Table). Cesium-133 is the only natural isotope (100% natural abundance). Cesium has no known biological role, but may substitute for potassium and so is relatively easily assimilated by biological systems. Three of the numerous artificial radioisotopes may be present in the environment: ^{135}Cs , ^{134}Cs and ^{137}Cs . The first of these is a component of long-lived fission product ($\tau_{1/2} = 3 \times 10^6$ years) that is a low-energy β -emitter. As a component of nuclear waste, there is a risk of its release into the environment. The other isotopes have been released by atmospheric fallout caused by nuclear weapons testing in the 1950s and 1960s and by accidental releases particularly at Chernobyl in 1986 and Fukushima in 2011. They are both γ - and β -emitters, with half-lives of 2.07 years for ^{134}Cs and 30.2 years for ^{137}Cs .

Cesium is the most widely studied radionuclide because of the presence of ^{137}Cs (and to a lesser extent ^{134}Cs) in both atmospheric fallout from weapons testing in the 1950s and 1960s and from the notorious accidents at Chernobyl and Fukushima. Atmospheric fallout from weapons testing has made ^{137}Cs an important and widely used marker of soil erosion. By comparison most fallout from Chernobyl and Fukushima occurred over much shorter times shortly after the events and therefore the distribution was more heterogeneous and dependent on rainfall. The relation between climate and soil type had important consequences on the subsequent dynamics of radiocesium. Many high-rainfall areas affected by fallout were upland and peat dominated areas with small clay content, and this led to low fixation of Cs. This was highlighted after the Chernobyl accident, when some models predicted rapid strong fixation of Cs on soil and therefore low mobility and soil-to-plant transfer.

Cesium is reversibly adsorbed on negatively charged clay minerals. In general, clay minerals have a greater affinity for Cs than other cations present on the exchange complex, particularly divalent cations. This is coherent with cation exchange theory and arises from its valency and hydration energy. There is a marked concentration dependence of Cs adsorption on soils and clay minerals. Adsorption isotherms are non-linear, often being fitted to the Freundlich isotherm, with affinity decreasing with increasing concentration. The strong affinity at trace concentrations of Cs is ascribed to the marked affinity of a small proportion of adsorption sites on illites and weathered mica. These are known as frayed edge sites that collapse following adsorption of Cs with loss of the hydration water molecules (Cremers et al., 1988). This reaction is energetically favorable and thus essentially irreversible. These adsorption sites have been named "frayed edge sites" (FES). The concentration dependence of affinity for Cs is an indication of the heterogeneity of surfaces. Some authors assert that a small number of FES with distinct affinities exist, although there may be a continuum of sites with differing affinities. The most important consequence of this is that measurements made with stable Cs (thus at much greater concentrations than found in the environment) are not relevant to understanding or predicting environmental dynamics. Since radiocesium is present in trace amounts in soils, the amounts of micaceous minerals required to dominate the overall affinity are not directly quantifiable by direct methods. Cesium adsorption is thus not well predicted by clay content. Clay minerals in soils are associated with organic matter coatings. Organic matter has been shown to decrease the strong affinity of micaceous minerals for Cs (Staunton et al., 2002). This is thought to reflect a physical blockage of the FES, preventing their collapse and reducing the specific adsorption of Cs. The strong adsorption of Cs on soil limits its bioavailability, but conversely leads to a

significant contribution to contamination of the food chain by soil ingestion of grazing animals, particularly sheep in poor grazing conditions.

Soil potassium plays an important role in Cs dynamics in soil. Potassium competes with Cs both at biological membranes, inhibiting uptake, but also inversely at the soil exchange complex, limiting adsorption. Potassium fertilization is recommended to reduce radiocesium uptake by crops. In addition, excess soil potassium would reduce the depletion in the rhizosphere where K concentrations may be markedly smaller than in bulk soil, thus enhancing Cs uptake. The “radiocesium interception parameter” (RIP) is important for understanding Cs dynamics in the soil–plant system (Delvaux et al., 2000). It combines the limiting Cs-K selectivity coefficient and the abundance of FES. This parameter has been reported to enable a good prediction of the Cs distribution coefficient in soils.

Case study: Strontium

Strontium is an alkaline earth metal (Group II) that exists as a stable isotope, with a simple chemistry, similar to that of calcium. It has numerous radioactive isotopes, the most environmentally significant being ^{85}Sr , ^{89}Sr , and ^{90}Sr , with half-lives of 64.8 days, 50.5 days and 29.1 years respectively. Strontium-90, a beta-emitter in common with Cs, has been introduced into the environment by fallout from atmospheric testing and by accidental releases. Soil contamination of the two elements are often reported together. However Sr contents are considerably smaller than those of Cs and cause little environmental concern. Strontium is adsorbed by soil components and this adsorption is easily reversible. There is little biological discrimination between Sr and Ca, therefore Sr is found in milk and other animal products, and once absorbed may be accumulated in bone. There are no effective countermeasures against radiostrontium contamination of soil.

Case study: Radon

Radon is the most widely studied natural radioelement in soil science and radioecology. Soil acts as both a source, a barrier and a brake to the diffusion of radon. Unlike other radioelements of environmental concern radon is a gas, the heaviest element in the noble gas group of the periodic table. Fig. 2 shows the decay chain of uranium, highlighting the decay chain of radon, the only gaseous element in the chain. All its isotopes are radioactive and the most commonly studied is ^{222}Rn , an alpha-emitter, with a half-life of 3.8 days. It is formed as one of the progeny of the uranium decay chain originating from the disintegration of uranium-238, known as the uranium or radium series. To a large extent, the risk of exposure to radon depends on the geology of an area, with large global and national variations. Greatest amounts of radon are found in granitic or volcanic areas. Large regional differences are reported in human exposure to radiation from radon, for example there is factor of 2 between the radiation dose due to radon in Brittany compared with the French national average dose, and similarly a factor of 5 between doses in Cornwall and on average in the UK. Radon may accumulate in mines and other enclosed underground places such as caves and basements. Although the cause was not understood, the illness due to high radon exposure in mines has been known for centuries: the wasting disease of miners was named *mala metallorum* by Paracelsus in 1530. As a noble gas there is little chemical interaction between soil and radon. Nevertheless, soil, in particular soil texture, plays an important role in attenuating exposure to radon. The porosity and permeability

Fig. 2 Decay chain of ^{238}U , giving half-lives and major radiation, highlighting the decay chain of one of its progeny, ^{222}Rn .

of soil determine the emanation of radon at the surface. Clay rich soils and subsoils slow radon diffusion, and so a greater proportion decays to form non-gaseous progeny before reaching the surface. Emanation of radon also varies with soil humidity, because of the volume fraction and tortuosity of air-filled pores. These may result in a bell shaped relation between radon emanation and soil humidity.

Case study: Halogens

Two elements of the halogen group exist as radioisotopes of environmental concern; chlorine and iodine. Chlorine has two stable isotopes and 14 radioactive isotopes with atomic masses between 32 and 43. One of these, ^{36}Cl , is a predominantly beta-emitter with a half-life of 3×10^5 years. There are both natural and artificial sources of this isotope in the environment. The natural sources include interactions of argon, potassium and calcium with cosmic radiation and underground neutron activation of ^{36}Cl with neutrons produced in the uranium decay series. Chlorine-36 has been used as a geological dating technique for rocks. It is produced within nuclear reactors and thus may be released during retreatment and waste disposal. It was also present in atmospheric fallout following weapons testing during the 1950s and 1960s. Amounts of ^{36}Cl from natural and artificial sources are of approximately the same order, and it is therefore difficult to quantify contamination with certainty. The chemistry of radiochlorine is largely identical to that of chloride, a very mobile, sparingly adsorbed, anion. Iodine is a heavier element of the halogen group. It has 25 isotopes, with atomic masses between 117 and 141, and only ^{127}I is stable. Two of the radioisotopes have half-lives sufficiently long to be of environmental concern; ^{131}I and ^{129}I with half-lives of 8 days and 1.57×10^7 years respectively. Both emit both β^- and electromagnetic radiation. Some ^{129}I is produced naturally by some fission reactions and persists because of its long half-life. Both isotopes are produced in nuclear reactors, considerably more ^{131}I than ^{129}I and have been introduced into the environment as tolerated discharges, waste disposal, fallout from atmospheric weapons testing in the 1950s and 1960s and from accidents. Given the difference in half-lives only ^{129}I remains in discharges or from fallout. However, the presence of ^{131}I in accidental releases such as following the accidents at Chernobyl and Fukushima presented risks of human exposure with fixation of radioiodine to the thyroid. This may be counteracted by administration of stable iodine to saturate the thyroid gland. The dominant pathway of human contamination by radioiodine following the Chernobyl accident was by milk consumption, and particularly affected children. In contrast, the main pathway of contamination after Fukushima was air inhalation. The chemistry of iodine is more complex than that of chlorine, with a more extensive organic and redox chemistry. It is therefore less mobile in the environment and its dynamics less simple to predict and model.

Conclusions

In conclusion, the dynamics of radionuclides in soil are controlled by similar processes as for other natural or artificial contaminants. The major differences arise from the risk of external exposure, in addition to toxicity following absorption. Soil may be a source of radioactivity, as well as a physical barrier to radiation and to the mobility of radionuclides. Radioactivity may be of natural or man-made origin, and in many countries the exposure to natural radiation accounts for a large proportion of exposure, although this includes radon against which preventive measures can be taken.

Abstract

Carbon (C), silicon (Si) and germanium (Ge) are members of the Group 14 elements; C is a non-metal while Si and Ge are metalloids. All have a strong propensity for covalent bonding. Their oxides (CO_2 , SiO_2 , GeO_2) dissolve to form weak acids in aqueous media. Carbon is abundant in the atmosphere and essential to life. Silicon is ubiquitous in the Earth's crust and beneficial to plants, while Ge is a non-essential microelement. Inorganic C, Si and Ge constitute a trilogy of great interest in soil science and biogeochemistry: C and Si interact closely in terrestrial, marine and global biogeochemical cycles, while Ge is a relevant tracer for Si in these cycles.

Key points

- Inorganic C forms in soils
- Role of carbonate and silicate minerals in soil buffering and acid neutralizing capacity
- Fate of silicon in the soil–plant system (weathering, clay formation, silica sorption, silica uptake)
- Biogeochemical cycle of silicon and carbon–silicon interactions
- Germanium as a tracer of silicon cycles

Introduction

The Group 14 elements have a ns^2np^2 electronic configuration, and they show an increasing metallic character from the lightest to heaviest. Carbon (C) is a non-metal while silicon (Si) and germanium (Ge) are metalloids, and all have a strong propensity for covalent bonding. Their oxides (CO_2 , SiO_2 , GeO_2) dissolve to form weak acids in aqueous media ($\text{pK}_a \geq 6.4$). Their exceptional properties make both natural and artificial intelligence possible: C is at the center of natural intelligence and life, while Si and Ge are at the core of artificial intelligence and electronic technology. Carbon is abundant globally and is essential for life itself; it forms so many natural compounds that it makes up the domain of organic chemistry. Silicon is ubiquitous in the Earth's crust, is beneficial to plants, essential to diatoms, and crucial for smart agriculture, while Ge is a microelement used to trace Si fluxes in ecosystems. This chapter deals with the inorganic chemistry of these elements in soil, with a focus on solid–liquid interactions in the soil–plant system.

Inorganic C forms in soil

The addition of C substances to soil occurs chiefly through the deposition of dead biomass from plant photosynthetic production. In soil, C substances are consumed by living organisms whose respiration produces CO_2 and CH_4 in aerobic and anaerobic conditions, respectively. Carbon dioxide (CO_2) is widespread in the gaseous phase of well-drained soils, but it can give way to methane (CH_4) in poorly-drained, reduced soils. Wetland soils constitute the largest source of CH_4 entering the atmosphere, emitting about one-third of the global total; rice paddy soils are the major emitters (Sposito, 2016).

The presence of CO_2 in soil air can have a significant effect on soil acidity and mineral weathering by releasing H^+ ions through the following reactions:

where non-volatile carbonic acid H_2CO_3^* designates the sum of H_2CO_3 and aqueous CO_2 , and K is the equilibrium constant at 25 °C (Lindsay, 1979). Reactions (1) to (3) show that H_2CO_3^* is a major source of protons in the soil solution, making HCO_3^- (bicarbonate) an ubiquitous soil solution species under aerobic conditions because it is the major aqueous carbonate species in dilute solution (Stumm and Morgan, 1996). The degree of CO_2 impact on proton release, however, depends on (i) temperature, (ii) CO_2 partial pressure (P_{CO_2}), (iii) proton consumption and or HCO_3^- and CO_3^{2-} leaching, (iv) precipitation of carbonates and or evaporites (Stumm and Morgan, 1996). These four points are briefly discussed hereafter. (i) A decrease in temperature shifts reaction (1) to the right ($K_{\text{CO}_2} = 10^{-1.2}$ at 5 °C) (Stumm and Morgan, 1996). (ii) At atmospheric air pressure, $P_{\text{CO}_2} \approx 10^{-3.52}$ atm ($10^{-1.51}$ kPa), pH = 5.7 in deionized water, but once P_{CO_2} reaches $\approx 10^{-2}$ atm (1.01 kPa) from, for example, intense biological activity in soil, pH = 4.9. (iii) Proton (H^+) consumption by mineral weathering or H^+ adsorption on the soil exchange complex, and leaching of HCO_3^- and or CO_3^{2-} (carbonate) anions, move reactions (2) and (3) to the right, favoring additional H^+ release. Proton adsorption by clay minerals induces their dissolution and aluminum (Al) release. (iv) The precipitation of CaCO_3 (calcium carbonate) occurs as follows:

In semiarid or arid environments, where evaporation exceeds rainfall and accounts for major soil water loss, oversaturation of the soil solution with CO_3^{2-} and or HCO_3^- ions (depending on pH) results in the precipitation of secondary calcium (Ca) and or magnesium (Mg) carbonates (Sposito, 2016), e.g., calcite (CaCO_3) as shown by reaction (4), dolomite ($\text{CaMg}(\text{CO}_3)_2$), magnesite (MgCO_3), and or evaporites, e.g., nahcolite (NaHCO_3), natrite (Na_2CO_3). Reactions (1), (2), and (4) indicate that the precipitation of CaCO_3 (calcite) depends on P_{CO_2} , $[\text{Ca}^{2+}]$ and pH, where [solute] means solute concentration. At common P_{CO_2} and $[\text{Ca}^{2+}]$ values, calcite precipitates at pH around 7.8–8.5. Oversaturation of the soil solution enhances the formation of carbonates and evaporites, increasing the acid neutralizing capacity (ANC) of soils (van Breemen et al., 1983), which then undergo net alkalization (Fig. 1a), which arises in some Solonchaks, Gypsisols, Calcisols and Durisols (IUSS, 2015).

Conversely, Ca and Mg carbonates can be inherited from the soil parent material and dissolve, as described in the reverse reaction (4), in soils under wetter conditions. In environments where evaporation balances rainfall, both dissolution and precipitation processes may occur within the same annual cycle. An exemplary case concerns the seasonal dynamics of CaCO_3 in some soils under semiarid or subhumid continental environments, e.g., certain Calcisols, Kastanozems, Chernozems and Vertisols (IUSS, 2015). In these environments, spring moisture and increased temperature stimulate biological activity in the topsoil, resulting in an increase in P_{CO_2} , which moves reactions (1) and (2) to the right, leading to CaCO_3 dissolution as described in the reverse reaction (4). The solutions enriched in HCO_3^- and or CO_3^{2-} ions migrate to the subsoil horizons, but they are driven

Fig. 1 (a–c) Schematic representation of the impact of the annual rainfall–evaporation balance on soil carbonate equilibria, illustrating the role of CaCO_3 as a privileged proton consumer that can protect other weatherable minerals of lower solubility and/or dissolution rate in well-drained soils (c). (d) Same representation illustrating silicate dissolution (forsterite): aqueous H_4SiO_4 can be leached and involved in precipitation or sorption processes, and is taken up by plants. The Acid Neutralizing Capacity (ANC) is here evaluated on an annual basis as the difference $[\text{ANC}_{\text{yr}+1} - \text{ANC}_{\text{yr}}]$ (van Breemen et al., 1983).

upwards by capillarity to upper horizons with water loss in the dry and hot summer. Then, oversaturation results in CaCO_3 precipitation along pore walls, giving rise to particular forms of deposits (soft powdery lime, pseudomycelium) and partial pore clogging (IUSS, 2015). This process keeps the ANC constant on an annual basis (Fig. 1b), making these soils geochemically conservative, where calcite may appear as a primary mineral as well as pedogenic CaCO_3 .

In well-drained soils under sub-humid and humid environments where rainfall exceeds evaporation, the aqueous alkalinity, which is largely attributed to HCO_3^- activity, is leached out with base cations and further transferred to watersheds and rivers, thus into the hydrosystem (Fig. 1c). This results in a decrease in ANC and thus soil net acidification, while soil solution pH remains constant as long as H^+ ions are consumed by CaCO_3 (van Breemen et al., 1983).

Thus, considering Dokoutchaïev's global zonality, the latitudinal distribution of soils derived from calcareous parent materials depends strongly on the fate of carbonate in both its precipitated and aqueous forms, which are principally controlled by water balance and biological activity. Consequently, from arid and semi-arid environments to subhumid and humid environments, the soil cover changes globally from e.g., Solonchak, Calcisol to Kastanozem, Chernozem, and eventually to decarbonated Phaeozem, Umbrisol, Luvisol, as illustrated schematically in Fig. 1a–c (IUSS, 2015). In carbonated soils, CaCO_3 can be seen as a privileged proton consumer, the protective effect of which can retard the dissolution of weatherable silicate minerals, which have very slow dissolution kinetics (Fig. 1c–d).

Carbon–silicon interactions

Inorganic carbon forms in the soil solid, liquid and gaseous phases are thus clearly pivotal in the processes of net acidification and alkalization of soil, and in pH buffering (Fig. 1a–c). Atmospheric CO_2 concentration can be regulated by silicate weathering that transforms CO_2 into carbonate alkalinity and releases monosilicic acid (H_4SiO_4), as illustrated for forsterite, a primary mineral representing the Mg endmember of olivine (Fig. 1d), following the reactions below:

Combining reactions (1), (2) and (5) gives:

Thus, 4 mol $\text{CO}_2(\text{g})$ react with 1 mol forsterite to form 1 mol H_4SiO_4 and release aqueous bicarbonate and base cation, the leaching of which moves reaction (6) to the right, which emphasizes the contribution of weatherable silicate minerals to ANC (Fig. 1d). The global biogeochemical cycles of C and Si thus interplay through silicate weathering on continents and C fixation by diatoms in marine ecosystems (Erhart, 1963). Silicate weathering consumes CO_2 if soil conditions enhance the dissociation of H_2CO_3^* and solute leaching, exporting aqueous H_4SiO_4 toward watersheds, rivers and oceans (Fig. 1d). In marine ecosystems, siliceous diatoms take up Si as a nutrient, precipitating approximately $6.7 \cdot 10^{12}$ kg Si yr^{-1} , while fixing CO_2 , which contributes roughly half of net primary production of C ($26 \cdot 10^{12}$ kg C yr^{-1}) (Conley, 2002). Thus, the annual mobilization of Si and C by marine diatom biomass corresponds to a Si:C molar ratio of ~ 0.11 mol mol^{-1} . In terrestrial ecosystems, the global net primary production by photosynthesis is about $60 \cdot 10^{12}$ kg C yr^{-1} while plants accumulate Si in the range of ~ 1.6 – $5.6 \cdot 10^{12}$ kg Si yr^{-1} , noting that roughly 55% of the photosynthetic production is attributed to plants accumulating Si actively (Conley, 2002). The annual mobilization of C and Si by plants corresponds to a Si:C molar ratio ranging between ~ 0.012 and ~ 0.04 mol mol^{-1} .

Given that the biological cycle of Si is critical in primary productivity and C cycling in both terrestrial and marine ecosystems (Conley and Carey, 2015), and that Si uptake by plants improves their vigor and health (Coskun et al., 2019), the fate of inorganic C and Si forms in soil is at the core of major challenges facing global change and sustainable agriculture. Fig. 2 shows that the C and Si cycles have a connecting point in soil once protons released by H_2CO_3^* dissociation are consumed by silicate weathering. This connection also holds for other proton donors released during the aerobic decomposition of dead biomass, such as organic and nitric acids, and also, but more indirectly, by the extrusion of protons from plant roots (van Breemen et al., 1983). While inorganic C can be present in all three soil phases (Figs. 1 and 2), forms of Si are distributed exclusively between the liquid and solid phases (Fig. 2). The latter hosts an impressive diversity of Si-bearing minerals, whereas H_4SiO_4 is the quasi-unique Si species in the soil solution. The large $\text{pK}_{\text{a}1}$ value of the first ionization of H_4SiO_4 ($\text{pK}_{\text{a}1} = 9.8$ – 9.9) largely restricts its dissociation: about 90% of dissolved monosilicic acid is undissociated at pH ~ 9 . This suggests that, unlike H_2CO_3^* and its dissociated products, H_4SiO_4 does not contribute to ANC at the common pH values of soil solutions (van Breemen et al., 1983). Another major fact illustrated in Fig. 2 is that, unlike inorganic C, Si is substantially taken up from soil solution by vegetation in amounts that are similar to macronutrient concentrations in plants, but without being substantially incorporated into organic substances (Coskun et al., 2019). Instead, silica mostly precipitates in plant tissues as phytoliths, which are amorphous biogenic opal-A ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$).

Silicon in the soil–plant system

Distribution of silicon

Silicon is the second most mass-abundant element ($\sim 31\%$) in the Earth's crust after oxygen ($\sim 49\%$) and before aluminum (Al) ($\sim 8\%$) and iron (Fe) ($\sim 5\%$). By volume, over 90% of the Earth's crust is made up of SiO_2 and silicates. Silicon is thus omnipresent

Fig. 2 Schematic view illustrating some major aspects of the fate of inorganic forms of C and Si in a freely drained soil undergoing net acidification ($\text{ANC} < 0$). Inorganic C (left) occurs in the three soil phases while Si (right) is present exclusively in the liquid and solid phases. Aqueous H_4SiO_4 can follow four routes: mineral neoformation, sorption by oxides, uptake by biota, transfer to the hydrosystem. The Al-Si minerals encompass the aluminosilicates, here anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$) and kaolinite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$). Plant $\text{SiO}_2 \cdot n\text{H}_2\text{O}$ refers here to phytolith (opal-A), a biogenic Si form. The reactive surfaces that sorb aqueous H_4SiO_4 are figured here by an iron oxide, for example goethite ($\alpha\text{-FeOOH}$).

in nature and ubiquitous in rocks, sediments and soils, where it occurs in a huge number of silica, silicate and aluminosilicate minerals (Monger and Kelly, 2002). In these minerals, Si is exclusively in the IV valence state, and it exists only as a silicate tetrahedron, SiO_4^{4-} . In all these minerals, Si^{IV} bonds to the oxygen (O) atom, through which it links with other metals, the most common one being Al. Therefore, Si^{IV} does not bond directly with other Si^{IV} atoms or with other metals. This binding behavior differs greatly from that of C, which can form direct bonds with other C atoms. In soil, Si occurs exclusively in its solid and liquid phases. The total Si content depends on soil mineralogy and ranges from 5 to 470 g kg^{-1} whereas the content of aqueous Si varies from $3 \cdot 10^{-3}$ to $4.5 \cdot 10^{-1} \text{ g kg}^{-1}$ (Cornelis and Delvaux, 2016, and references therein). Soil Si-bearing minerals encompass silicate and silica minerals, both crystalline and amorphous. Silicate minerals involve various primary and secondary minerals, among which aluminosilicates predominate globally, particularly as clay minerals either inherited from soil parent material, transformed or formed during pedogenesis. Silica minerals include the SiO_2 polymorphs (e.g., cristobalite, tridymite), quartz varieties and some opals (Monger and Kelly, 2002). Non-mineral forms of silica include biogenic opals (opal-A, $\text{SiO}_2 \cdot n\text{H}_2\text{O}$), which are widespread in soils (phytoliths) and riverine and marine ecosystems (diatoms, sponge spicules, radiolaria) (Monger and Kelly, 2002). In particular, phytoliths form in plant tissues following the root uptake of aqueous H_4SiO_4 from soil solution, its transfer to transpiration termini where it precipitates as biogenic opal (Coskun et al., 2019). The content of phytolithic Si in soils is estimated to range from 1 to 10 g kg^{-1} worldwide, but may be higher locally, although rarely exceeding 70 g kg^{-1} (Meunier et al., 2014).

Fig. 2 illustrates schematically, in its right part, the fate and distribution of Si in soils. This graph shows that the primary source of Si in the soil–plant system is the pool of weatherable Si-bearing primary minerals, represented here by anorthite, the Ca-plagioclase ($\text{CaAl}_2\text{Si}_2\text{O}_8$), the dissolution of which releases H_4SiO_4 . Fig. 2 shows that aqueous H_4SiO_4 , generally designated as dissolved silicon (DSi), can follow four routes: (i) coprecipitation with Al to form clay minerals (e.g., kaolinite ($\text{Si}_2\text{Al}_2\text{O}_5(\text{OH})_4$) in Fig. 2), (ii) adsorption onto the surfaces of Al and Fe (hydr)oxides, (iii) absorption by plants (or by other biota), where it forms biogenic silica, (iv) transfer to watersheds and rivers. These routes are complex pathways characterized by feedback and/or reverse processes.

Mineral weathering and clay formation

In the early stages of soil formation, the weathering of primary silicate minerals is the mandatory initial step that releases DSI into the soil solution. It begins with mineral dissolution, which is induced by protons or ligands that form strong complexes with metals (Sposito, 2016). Primary mineral dissolution is illustrated in Fig. 2 by the acid dissolution of anorthite following the reaction:

This reaction is promoted by the leaching or biological uptake of Ca^{2+} , the hydrolysis of detached Al, which produces H^+ ions, the complexation of Al with inorganic or organic ligands, the removal of Si through leaching or formation of secondary minerals, i.e., smectite, kaolinite and gibbsite through the respective reactions below:

Fig. 3 illustrates the solubility lines of anorthite and the above-mentioned secondary minerals in a stability diagram using gibbsite ($\text{Al}(\text{OH})_3$) as the reference stable mineral ($\log(\text{Al}^{3+}) + 3\text{pH} = 8.04$). The concentration of aqueous H_4SiO_4 , designated as $[\text{H}_4\text{SiO}_4]$, is kinetically controlled by the dissolution of primary silicate minerals (e.g., anorthite) and the precipitation–dissolution of secondary minerals that are more soluble than quartz ($\text{SiO}_2(\text{quartz})$; $[\text{H}_4\text{SiO}_4] = 10^{-4} \text{ M}$), and less soluble than amorphous silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$; $[\text{H}_4\text{SiO}_4] = 10^{-2.7} \text{ M}$). Reaction (8) requires the presence of aqueous Mg^{2+} and ferric (Fe^{3+}) ions as reactants that integrate the octahedral sheet of the smectite formed. Magnesium and Fe^{3+} ions can be released by the dissolution of primary minerals, e.g., ferromagnesian silicates such as olivine, pyroxene, amphibole or biotite. Reactions (8) to (10) show that $[\text{H}_4\text{SiO}_4]$ controls the nature of the secondary mineral formed (Fig. 3). The highest H_4SiO_4 concentration promotes the formation of smectite (reaction (8)), while its decrease favors the synthesis of kaolinite (reaction (9)) and finally gibbsite in strongly desilicated environments (reaction (10)), where H_4SiO_4 is strongly leached out and transferred to the hydrosystem (Figs. 1d and 2). Consequently, H_4SiO_4 concentration, which is rainfall-dependent, is one of the properties controlling the zonal distribution of soils notably in intertropical regions: in the wet tropics, highly weathered soils containing kaolinite, gibbsite and Fe (hydr)oxides predominate, while smectite-rich soils occur in subhumid environments, characterized by a marked dry season, which is conducive

Fig. 3 Stability diagram for reference anorthite, gibbsite, kaolinite, smectite and allophanes in the $\text{Al}_2\text{O}_3\text{--SiO}_2\text{--H}_2\text{O}$ system (Li et al., 2022). The solubility lines for anorthite, gibbsite, kaolinite, smectite, quartz and amorphous silica refer to Lindsay (1979). The allophane solubility lines were compiled for field allophane and synthetic allophanes with Si/Al ratio of 0.5 and 0.8 mol mol⁻¹, respectively, using the *K* values of reactions (15)–(17) (Dobrzyński, 2006). Following parameters were fixed when required: pH = 6.0; $[\text{Ca}^{2+}] = [\text{Mg}^{2+}] = 10^{-3} \text{ M}$; $\log[\text{Fe}^{3+}] = 2.7\text{--}3\text{pH}$.

to the concentration of DSi in the soil solution. Combining reactions (7) and (9) formulates both the dissolution of anorthite and the synthesis of kaolinite in a single reaction:

In soils with a constant annual ANC and/or undergoing net alkalization ($\text{ANC} \geq 0$), hydrolysis reactions can be reversible without leading to precipitation of the original primary mineral. Other secondary silicates can be formed such as pedogenic zeolites in salt-affected, alkaline soils, e.g.:

Pedogenic zeolites are, however, rare in soils. Under Mediterranean and/or semiarid conditions with enough water for weathering but not enough for intensive leaching ($\text{ANC} \sim 0$), silica may precipitate:

As with pedogenic carbonate, pedogenic silica precipitates in soil voids and contributes to pore clogging as observed in Durisols (IUSS, 2015), where its accumulation leads to cementation.

In soils undergoing net acidification, the dissolution–precipitation process (e.g., reaction (11)) is irreversible. Furthermore, any decrease in H_4SiO_4 concentration and pH makes the secondary minerals formed unstable. In such conditions, they can dissolve. Their respective dissolutions are formalized through the reverse reactions (8) and (9), which release aqueous H_4SiO_4 . Combining the reverse reaction (9) with reaction (10) further illustrates the dissolution of kaolinite and subsequent formation of gibbsite in humid, desilicated environments:

Thus, secondary crystalline clay minerals can act as sink and source of DSi in soil, as shown in Fig. 2 for kaolinite. The same is true for amorphous aluminosilicates such as allophanic substances following the reactions formulated below, for field allophane (reaction (15)) and synthetic allophanes with Si/Al atomic ratio 0.5 and 0.8, respectively (reactions (16) and (17)) (Dobrzyński, 2006):

Fig. 3 shows that, within usual ranges of pH values and $[\text{H}_4\text{SiO}_4]$ (10^{-5} – 10^{-3} M), allophanes are metastable with respect to smectite and kaolinite (Dobrzyński, 2006). In particular, at H_4SiO_4 concentration around 10^{-3} M, the solubility lines are narrowly aligned for both the anorthite and field allophane reported here. Experimental data suggest that allophanes do not have a true thermodynamic stability field in a phase diagram. Overall, allophanic substances are considered transient aluminosilicate phases in soil weathering processes (Dobrzyński, 2006). They are therefore an important potential source of DSi (Li et al., 2022) due to their metastable character and rapid dissolution, especially under acid conditions (reactions (15)–(17)). Their rate of dissolution is one order of magnitude higher than that of crystalline phases of similar composition. These transient phases are also considered to be the highly labile hydroxyaluminosilicate (HAS), which may dissolve and precipitate following seasonal dynamics; they play a central role in controlling H_4SiO_4 concentration as an alternative source and sink for DSi in soil, as observed in some grassland soils within the same year (White et al., 2012).

Adsorption of H_4SiO_4 onto oxide surfaces

The concentration of H_4SiO_4 in soil solution is primarily determined by the precipitation and dissolution of silicate minerals. However, it may be affected by its sorption onto secondary Al and Fe (hydr)oxides, here referred to as (Al, Fe) oxides. Fig. 2 shows that in addition to clay formation and uptake by biota, H_4SiO_4 may be withdrawn from the soil solution by adsorption onto (Al, Fe) oxides. Gibbsite formation requires the dissolution of aluminosilicates in wet, desilicated environments (reaction (14)), which are widespread in the humid tropics. Iron oxides are ubiquitous in soils at all latitudes, as their formation can follow several routes: mineral weathering, oxidation–reduction, hydrolysis, chelation, protolysis and biomineralization (Bigham et al., 2002). Available data from the literature on the adsorption of H_4SiO_4 concerns mainly gibbsite, goethite and ferrihydrite. The sorption process occurs through the interaction between H_4SiO_4 with the oxide surface OH groups through ligand exchange and the subsequent formation of a covalent Si–O–metal bond, resulting in inner-sphere complexation (Bowden et al., 1973; Sposito, 2016). This process may also occur with kaolinite, but to a considerably lesser extent.

Gibbsite and Fe oxides possess a variable surface charge depending on pH, electrolyte concentration and counterion valence. They can generate both cation and anion exchange capacity, i.e., CEC and AEC, as a consequence of H^+ and OH^- sorption from soil solution following the schematic, simplified reaction (Uehara and Gillman, 1985):

Fig. 4 Illustration of the specific sorption of aqueous H_4SiO_4 , H_2PO_4^- and metal cations M^{n+} on metal oxide surfaces that bear reactive OH groups. As adapted from Bowden JW, Bolland MDA, Posner, AM and Quirk, JP (1973) Generalized model for anion and cation adsorption at oxide surfaces. *Nature Physical Science* 245(145), 81–83.

The pH value at which the total net surface charge is zero is the point of zero charge (p.z.c.) (Sposito, 2016), also termed pH at the isoelectric point (pH_{IEP}). Gibbsite and Fe oxides have a p.z.c. that usually ranges between 7 and 10 (Uehara and Gillman, 1985). Therefore, they develop a positive surface charge, thus AEC, at common pH values in the soil solution. On (Al, Fe) oxide surfaces, the sorption of oxyanions of polyprotic acids, such as phosphate, molybdate, and arsenate, is maximum at low pH and decreases with increasing pH, unlike metal cations as illustrated in Fig. 4 (Bowden et al., 1973) because of the progressive pH-induced reversal of the net surface charge from AEC to CEC.

Fig. 4 shows that the adsorption of H_4SiO_4 peaks at $\text{pH} \sim 9$, and decreases at lower and higher pH values (Bowden et al., 1973; Hiemstra et al., 2007). Unlike phosphate oxyanions, H_4SiO_4 remains undissociated at pH below 9, meaning that its sorption is due only to the interaction of Si with the surface OH groups. Illustrating this process schematically predicts that a decrease in pH leads to a decrease in H_4SiO_4 sorption (Hiemstra et al., 2007):

The inner-sphere complexation of monomeric Si results in the formation of either a monodentate $\equiv\text{FeOH}-\text{FeOSi}(\text{OH})_3$ or a bidentate $\equiv\text{Fe}_2\text{O}_2\text{Si}(\text{OH})_2$ surface complex (Hiemstra et al., 2007; Hiemstra, 2018) (Fig. 2). It involves monomeric Si as the main adsorbed species at a low loading of aqueous Si ($< \sim 0.9$ mM). At higher loading of aqueous Si ($> \sim 0.9$ mM), Si-tetramer can form on goethite surfaces, whereas Si-oligomers (di, tri, or tetramer) form on ferrihydrite surfaces at H_4SiO_4 concentrations below those required for polymerization in solution (Hiemstra et al., 2007; Hiemstra, 2018). The siliceous nature of natural ferrihydrites is likely because of the formation of Si-oligomers at relatively high Si loadings, which can occur in weathering solutions (Hiemstra, 2018). At pH above 9, H_4SiO_4 dissociation releases anionic H_3SiO_4^- as the oxide surface becomes increasingly negatively charged, generating coulombic repulsion and a subsequent decrease in H_4SiO_4 sorption (Fig. 4).

The specific adsorption of H_4SiO_4 onto (Al, Fe) oxides is poorly reversible. As a result of Si sorption, the release of protons from the Si-enriched (Al, Fe) oxides generates a downward shift of the p.z.c., thus increasing the CEC, which also occurs for phosphate oxyanions and other specifically adsorbed solutes (Uehara and Gillman, 1985). Desorption of Si may occur in the presence of competitive solutes that are also specifically adsorbed onto (Al, Fe) oxides. The specific sorption sites of these soil oxides are subject to competition between different adsorptive aqueous species. In addition to H_4SiO_4 , some solutes of environmental and agronomic interest are, for example, aqueous organic anions, arsenate, fluoride, phosphate and molybdate. Arsenate and fluoride fixation onto (Al, Fe) oxides detoxifies soils and waters. Molybdenum is a plant micronutrient and is crucial for the optimal development of rhizobial symbiosis, a bioprocess that improves the nitrogen status of tropical legume crops. The competition between solutes for absorbing sites suggests that preloading the oxide surface with silicate may depress the sorption of competitive anions, depending on adsorbent selectivity and the surrounding conditions, notably pH and electrolyte concentration (Uehara and Gillman, 1985; Sposito, 2016). Conversely, organic and inorganic anions that are selectively adsorbed may displace Si and increase its mobility.

Silicate sorption can be exploited to amend oxide-rich soils (Ferralsols) to increase CEC and better regulate the bioavailability of phosphorus (P), P fixation being a major constraint in these soils (Uehara and Gillman, 1985), particularly at low pH (Fig. 4).

Aluminum and Fe oxides have been claimed to affect the fate of DSi strongly in soils because their surface OH groups interact specifically with H_4SiO_4 . This statement must be moderated by the three processes discussed above: (i) the weak reversibility of the process may limit subsequent Si sorption, (ii) the change of oxide composition due to inner-sphere complexation by the Si–O–metal bond shifts the value of the p.z.c. downwards, which also reduces further Si sorption, (iii) various solutes strongly compete with H_4SiO_4 for adsorption, which may significantly hamper the Si sorption process. On the other hand, the magnitude of the process depends on both the nature and content of (Al, Fe) oxides in soils. The oxide surface reactivity for oxyanions, weak acids and water is well known to decrease with increasing oxide crystallinity (Bigham et al., 2002). As crystallinity increases, oxide crystals become larger and surface area decreases. Thus, poorly crystalline, fine-sized Al and Fe oxides have a much larger specific surface area than their crystalline counterparts and adsorb larger amounts of H_4SiO_4 . In the range of $[\text{H}_4\text{SiO}_4]$ of 10^{-4} – $10^{-2.7}$ M, pure, poorly crystalline, fine-sized Fe oxide such as ferrihydrite would adsorb ~ 1 – $25 \mu\text{mol Si kg}^{-1}$ at pH 5.5. For instance, within a range of 1–10% ferrihydrite content in the soil, Si adsorption would theoretically amount to 0.01 – $2.5 \mu\text{mol Si kg}^{-1}$ soil, yielding a small amount of adsorption despite the absence of competitive adsorptive species. However, given the affinity of the surface OH groups of (Al, Fe) oxides for Si, the soil Si sorption capacity has been proposed as an index revealing both the nature and magnitude of soil surface properties, linked to their stage of weathering (Gallez et al., 1977), since end-stage weathering results in the relative accumulation of (Al, Fe) oxides for given parent materials. More generally, weathering promotes the relative accumulation of quartz and secondary (Al, Fe) oxides depending on the composition of soil parent material. Therefore, it is worth considering the effect of Si chemistry in soil on pH buffering.

Silicon in soil impacts pH buffering

Unlike (Al, Fe) oxides (p.z.c. ~ 7 – 10), Si oxides have a very low p.z.c. (2 – 2.5) (Monger and Kelly, 2002; Uehara and Gillman, 1985). These huge differences explain why highly weathered soils such as Acrisols and Ferralsols (IUSS, 2015), although both are strongly desaturated in base cations, differ widely in pH. The Nernst equation predicts that the p.z.c. value is the pH at which the surface potential is zero, corresponding to the point of maximal chemical stability (Uehara and Gillman, 1985). Thus, highly weathered, variable-charge soils tend to have pH values around their p.z.c., the value of which results from their contents of organic matter, kaolinite, (Al, Fe) oxides and residual quartz. This tendency for soil pH to drift toward the p.z.c. (pH_{IEP}) has been termed ‘isoelectric weathering’ by Mattson in 1932 (Uehara and Gillman, 1985). In well-drained soils undergoing net acidification ($\text{ANC} < 0$), weathering processes ultimately lead to the relative accumulation of residual quartz or secondary oxides (Al, Fe) depending on whether they are derived from siliceous felsic or mafic rocks. In the first case, highly weathered siliceous soils (Acrisols, Podzols) with low p.z.c. tend to be strongly acid ($\text{pH} \leq 4.5$), whereas highly leached soils rich in (Al, Fe) oxides with higher p.z.c. tend to be sub-neutral ($\text{pH} \sim 5.5$ – 6.5), as exemplified in some Brazilian Ferralsols or Hawaiian perhydrated Andosols (Uehara and Gillman, 1985). This is illustrated in Fig. 5, which schematically represents a hypothetical titration curve of theoretical soil materials illustrating the two routes described above: a decrease and an increase in pH in highly weathered soils depending on the nature of their dominant components. This graph also illustrates the importance of silicates and aluminosilicates, both primary and secondary, in buffering soil pH through their contribution to ANC.

Fig. 5 Schematic illustration of a hypothetical titration curve of theoretical well-drained calcareous soil materials by a strong acid. Progressive proton consumption by soil minerals leads to the dissolution of CaCO_3 , primary minerals, secondary clay minerals, and eventually the relative accumulation of oxides either quartz or (Al, Fe) oxides depending on the nature of soil parent siliceous/felsic or mafic, respectively. The weathering of siliceous/felsic and mafic rocks would indeed lead to the relative accumulation of quartz and (Al, Fe) oxides, respectively, making pH tending to p.z.c. according to the principle of isoelectric weathering (Uehara and Gillman, 1985). As adapted from van Breemen N, Mulder J and Driscoll CT (1983) Acidification and alkalization of soils. *Plant and Soil* 75, 283–308.

Once carbonates have been dissolved (reverse reaction (4)), pH buffering depends mostly on the weathering of primary and secondary silicate minerals (reactions (5), (7) and reverse reactions (8), (9), respectively) together with the adsorption of H^+ ions by clay minerals and organic matter (van Breemen et al., 1983). Reaction (11), which combines anorthite dissolution and kaolinite formation, shows the proton consumption through the transfer of H^+ ions from the weathering solution into the octahedral sheet of the clay mineral formed. At the final stages of weathering, the fate of Si is also critical for pH buffering. The relative accumulation of quartz gives rise to strongly acid soils such as Acrisols and Podzols (IUSS, 2015), whereas the heavy leaching of H_4SiO_4 limits the formation of kaolinite and promotes the relative accumulation of (Al, Fe) oxides. This contributes to the increase in soil pH in some Ferralsols and Andosols (IUSS, 2015), according to the principle of isoelectric weathering (Uehara and Gillman, 1985). In both cases, the soils are highly weathered and depleted in base cations and nutrients, but they largely differ in pH: the former are strongly acid ($pH \leq 4.5$), the latter are sub-neutral ($pH \approx 5.5$ – 6.5). Since the mineral source for mobile Al is lacking, Al toxicity does not occur readily in these highly weathered soils, contrary to a popular myth. Instead, this constraint is associated with clay mineral dissolution (Fig. 5).

Terrestrial biological cycle of silicon

As discussed above and illustrated in Fig. 4, dissolution and precipitation of soil silicate minerals first govern the concentration of aqueous H_4SiO_4 , and therefore the bioavailability of Si. However, plants also exert a control on $[H_4SiO_4]$ and Si fluxes through mineral weathering induced by root uptake, as well as phytolith formation, return and dissolution in soil. Thus, soil processes and Si biocycling interact considerably in soil–plant systems (Cornelis and Delvaux, 2016).

Plants play a crucial role in soil evolution by promoting silicate weathering through cation uptake and proton extrusion by roots, and by forming phytoliths that can dissolve in soils:

Reaction (20) indicates that H_4SiO_4 undersaturation is the driving force for dissolving amorphous silica. But temperature and electrolyte concentration also strongly affect the dissolution kinetics, as observed for quartz (Dove et al., 2008). At 25 °C, the rate of dissolution of phytoliths depends strongly on pH; it increases by two orders of magnitude from pH 3 to 8 (Frayse et al., 2009). At common pH values of soil solutions, the rate of dissolution of phytoliths is 10^2 – 10^4 higher than that of crystalline clay minerals and primary mafic silicates and feldspars (Frayse et al., 2009), but is similar to that of amorphous minerals in soils (Li et al., 2022). However, their dissolution in soils can be affected by both phytolith properties and soil conditions or processes, among others: phytolith size, morphology and specific surface area, entrapment in soil aggregates, protection by Al and Fe coatings (Li et al., 2022, and references therein).

Fig. 2 indicates that plants act as Si sinks and sources in soil–plant systems. However, their quantitative contribution to the biological cycle of silicon in terrestrial ecosystems depends on the mineral reserve of the soil (illustrated in Fig. 2 by anorthite), and therefore on its degree of weathering. The net acidification of soil results in the progressive depletion of primary and secondary silicate minerals (Fig. 5). Therefore, with increasing weathering and soil development, advanced desilication depletes the mineral source of DSi, and hence phytoliths progressively become the major source of bioavailable Si in soil (Lucas et al., 1993; Meunier et al., 1999). In other words, the biological Si feedback loop progressively takes over the Si plant uptake from weatherable primary and secondary minerals.

Paradoxically, Si biocycling is more intense in soils depleted in weatherable minerals, as illustrated in Fig. 6. There are two major reasons for this observation: (i) the depletion of silicate minerals, (ii) the rate of dissolution of phytoliths, which is much greater than that of most soil silicate minerals at common pH values of the soil solution. In this respect, the restitution of phytolithic Si to soil through the deposition of dead biomass may alleviate desilication through the control exerted by (H_4SiO_4) on mineral stability (see for example, Eqs. (7)–(10) and (14)–(17)). Plants may therefore have a dual role in Si cycling in soil–plant systems: (i) they enhance mineral dissolution through root uptake, (ii) they build up the pool of phytolithic Si in soil, which favors the stability of clay minerals through phytolith control on aqueous H_4SiO_4 (Lucas et al., 1993). By converting mineral Si into phytolithic Si, plants increase the mobility of Si in terrestrial ecosystems and alleviate desilication in topsoils (Lucas et al., 1993; Meunier et al., 1999). Although not essential to plants, silicon is therefore an essential link between the mineral and living worlds. Moreover, its assimilation by plants alleviates biotic and abiotic constraints that reduce crop yields in several agrosystems where the management of Si fluxes from soil to plant can be crucial for sustainable farming and smart agriculture.

Germanium

Germanium is analogous to silicon

Germanium (Ge) is widespread in the Earth's crust where it ranks as the 54th most abundant element with a concentration estimated at 1.3–1.6 $\mu g\ g^{-1}$. From the position of Ge in the periodic table, Mendeleev had predicted its existence and some of its properties, and called it 'ekasilicon.' The similarities between Ge and Si are remarkable. They are due to their identical outer electron structures, similar ionic radii (Si^{4+} : 0.04 nm, Ge^{4+} : 0.053 nm), and tetrahedral bond lengths (Ge–O: 0.175 nm; Si–O: 0.164 nm).

Fig. 6 Schematic illustration of the variation of Si uptake rate by natural vegetation as influenced by soil weathering stage (arbitrary units). The Si uptake rate was measured in the following ecosystems: forest and prairie in Leptosol, Regosol, Kastanozem; forest in Cambisol, prairie in Chernozem and Phaeozem; rainforest in Ferralsol and savanna in Lixisol; bamboo forest in Podzol. The respective figures associated with the respective reference soil groups (IUSS, 2015) are the average values of Si uptake from literature data. The hatched rectangle represents the set of collected data, excluding the exceptional, unusual Si uptake rate measured in a Podzol, in which the eluvial E horizon is a 15-cm-thick phytolithic material developed at the expense of highly weathered trachytic ashes (Meunier et al., 1999). Adapted from Table 1 in Cornelis JT and Delvaux B (2016) Soil processes drive the biological silicon feedback loop. *Functional Ecology* 30(8), 1298–1310. and references cited therein.

Germanates and silicates thus form isostructural compounds in the Earth's crust (Wiche et al., 2018, and references therein). Most importantly, however, trace Ge readily substitutes for Si in the silicate tetrahedron SiO_4^{4-} .

Germanium in the soil–plant system

Being analog to Si, most Ge in the Earth's crust occurs in primary silicate minerals in rocks and eventually in secondary silicates in soils. The variation in Ge concentration ($1.6\text{--}0.9\ \mu\text{g g}^{-1}$) follows that of Si and thus in the following sequence: granites, siliceous rocks > mafic rocks > ultramafic rocks (Wiche et al., 2018). With increasing weathering and soil development, fractionation and sequestration of Ge relative to Si may occur which eventually leads to the formation of Ge-containing secondary minerals, as predicted by reaction (11) for Si. The dissolution of both primary and secondary minerals releases aqueous H_4SiO_4 (Fig. 2; reactions (5), (7), (15), (16), (17); reverse reactions (8), (9)), and H_4GeO_4 , which is thus ubiquitous in trace concentrations in both weathering and soil solutions. Germanic acid (H_4GeO_4) is a weak acid, with a large $\text{p}K_{a1}$ value for the first ionization of H_4GeO_4 ($\text{p}K_{a1} \sim 9.3$). In aqueous solutions, monomeric undissociated H_4GeO_4 is, by far, the dominant inorganic species of Ge, and has a first dissociation constant similar to that of monomeric silicic acid H_4SiO_4 . However, the behavior of aqueous Si and Ge may differ because Ge can form stable complexes with carboxylic acids and phenolic groups in acidic and neutral or basic solutions, respectively (Wiche et al., 2018), likely due to the increased metallic character of Ge compared to Si. Depending on the nature of mineral phases that control $[\text{H}_4\text{SiO}_4]$ in the liquid phase (Fig. 3), the orders of magnitude of $[\text{H}_4\text{SiO}_4]$ and $[\text{H}_4\text{GeO}_4]$ in weathering and soil solutions would be mostly within the ranges $10^{-3}\text{--}10^{-5}$ and $10^{-6}\text{--}10^{-8}$ M, respectively. The root uptake of Ge and Si are similar in hydroponically grown plants. Germanium is not a plant nutrient, nor a strongly toxic element in the environment. However, at concentrations around $1\ \text{mg l}^{-1}$ in the nutrient solution, Ge induces toxic symptoms in Si accumulators such as rice (*Oryza sativa* L.). Plant Ge in biomass is likely to be associated with biogenic Si in phytoliths. Similar to H_4SiO_4 , H_4GeO_4 may be withdrawn from the soil solution by being adsorbed onto secondary (Al, Fe) oxides. Similar to Si, the sorption of Ge onto Fe oxide strongly increases with increasing pH to a maximum at pH 9. In some highly weathered soils in the tropics, the upper iron-rich horizons can be significantly enriched in Ge indicating adsorption on Fe oxides.

The atomic Ge/Si ratio as a powerful biogeochemical proxy

Germanium closely follows the properties and behavior of Si, and is thus considered a tracer of Si in biogeochemical cycles. Overall, Fig. 2 describes the routes followed by both Si and trace Ge in the soil–plant system. Data in the literature extensively illustrate the use of the atomic Ge/Si ratio ($\mu\text{mol mol}^{-1}$) to trace Si in continental, oceanic and global cycles, but also to determine changes in

weathering over time. In this respect, the monitoring of the Ge/Si ratio in the different Si reservoirs can substitute the use of stable Si isotopes (^{28}Si , ^{29}Si , ^{30}Si) to study Si fluxes and cycles. Particularly in terrestrial ecosystems, the Ge/Si ratio gives a sharp distinction between plant uptake and clay formation (Fig. 2).

The Ge/Si ratio is around $2\ \mu\text{mol mol}^{-1}$ in most silicate rocks, but this value covers a substantial range, from 0.5 in quartz to $5\ \mu\text{mol mol}^{-1}$ in some primary aluminosilicates. Compared to this average value, the Ge/Si ratio increases significantly in the secondary soil silicates ($>4\ \mu\text{mol mol}^{-1}$), revealing the preferential partitioning of Ge relative to Si into clay minerals. As a result, weathering and soil solutions, and drainage waters and rivers have typically lower values ($\text{Ge/Si} < 1\ \mu\text{mol mol}^{-1}$). Most plant Ge/Si measurements are performed on extracted phytoliths rather than on bulk tissues. Phytoliths typically have Ge/Si values below $1\ \mu\text{mol mol}^{-1}$; most available Ge/Si values range between 0.003 and $0.5\ \mu\text{mol mol}^{-1}$. The Ge/Si atomic ratio is a highly relevant biogeochemical proxy for tracing Si fluxes and cycles.

Conclusion

The inorganic forms of carbon, silicon, and germanium, all non-metallic elements of Group 14, constitute a trilogy of vital interest in soil science and biogeochemistry because they are at the crossroads of the living and mineral worlds. Carbon and silicon interact closely in terrestrial, marine and global biogeochemical cycles, while germanium is a relevant tracer for silicon in these same cycles. In terrestrial ecosystems, together with soil organic matter, inorganic forms of carbon and silicon exert a major control over the buffering capacity of soils.

The future of research on inorganic C, Si, and Ge dynamics in soil is a challenge beyond the scope of this contribution because of the specificity of each of these elements. Nevertheless, substantial progress could be made by integrating advances in soil science, including biotic and abiotic processes, plant physiology, biogeochemistry, and ecology to improve our overview of C–Si interactions at the ecosystem level while using Ge as a tracer for Si fluxes. Such advances will help to define better the ecosystem services provided by silicon and carbon–silicon interactions in order to propose appropriate management practices to improve the sustainability of agroecosystems.

Abstract

The application of chemical equilibrium to soils and soil solutions is a potentially flexible tool, allowing the user to interpret experimental data and predict chemical changes after perturbations. Geochemical models are widely available to assist in this practice but require an understanding of fundamental concepts and an appreciation of the limitations to assumptions of equilibrium. This chapter establishes thermodynamic principles, discusses the importance of kinetics of reactions, examines shortcomings of applying these concepts in soils, and presents published applications of the approach.

Key points

- Basic concepts of chemical equilibria in soils are developed
- Chemical equilibria in soils have kinetic and thermodynamic requirements
- Equilibrium concepts can be applied to soils but challenges exist
- Geochemical modeling can be a powerful tool when the limitations are understood

Nomenclature

μ_i	Chemical potential of species i
μ_i°	Standard chemical potential of species i
DTPA	Diethylenetriamine pentaacetic acid
Equilibrium	A state of balance in a chemical reaction in which the concentrations of the reactants and products are no longer changing and in which minimum free energy has been attained
IAP	Ion activity product. The mathematical result of inserting measured or calculated activities of species into an equilibrium expression, including stoichiometric coefficients.
k	Rate constant
K_{eq}^c	Conditional equilibrium constant, based on concentrations of species
K_{eq}°	Thermodynamic equilibrium constant, based on activities of species
Redox	Oxidation/reduction
Solubility constant	Thermodynamic equilibrium constant for the dissolution of a solid phase

Steady state	A balance in an experimentally observed chemical reaction in which the concentrations of the reactants and products appear to be unchanging with time. Steady state differs from equilibrium in that the minimum free energy for a given reaction has not been achieved
Stoichiometry	The relative quantities (in moles) of products and reactants in a chemical reaction are indicated by the coefficients in the balanced chemical equation
ν_x	Rate of reaction. Forward reaction: $x = f$; reverse reaction $x = r$

Introduction

Although soils are dynamic, complex, and living systems, they are composed of identifiable minerals, amorphous compounds, and discrete ionic species that can be quantified. Solubilities, solid-phase transformations, dissolution of gases, and changes in oxidation state can be predicted by chemical thermodynamics. However, implicit in the application of these principles to soils is that the soil system (or, at the very least, the constituents in question) are in chemical equilibrium. If the assumption of equilibrium is valid, then we have the means at our disposal to describe the chemical behavior of the solid, liquid, and gas phases in soil. The challenges in applying chemical equilibrium to soils include: (1) identifying phases in the soil involved in the reactions; (2) developing the equilibrium concepts; (3) determining if equilibrium can be applied to systems of interest.

Definitions of chemical equilibrium

Before discussing chemical equilibrium in soils, we must clearly understand the concept. Two basic definitions of chemical equilibrium will be discussed: kinetic and free energy. The two definitions express the same phenomenon in different ways and allow us to understand better the constraints on equilibria in soils.

Kinetic definition

Consider a generalized chemical reaction in which A and B react to form products C and D with stoichiometric coefficients a, b, c, and d:

The rate of the forward reaction (from left to right) is given by:

$$v_f = k_f[A]^a[B]^b \quad (2)$$

in which $[x]$ represents the solution concentration of component x , and k_f is the forward rate constant. The rate expression for the reverse reaction is given by:

$$v_r = k_r[C]^c[D]^d, \quad (3)$$

where k_r is the rate constant for the reverse reaction. When only the reactants are present, the forward reaction proceeds relatively quickly. As products begin to accumulate, the reverse reaction occurs simultaneously, and the progress of the reaction slows. Eventually, the point will be reached in which the forward and reverse reactions are proceeding at the same rate, and the concentrations of the reactants and products will not change with time. This is the point of a dynamic, chemical equilibrium. When the forward and reverse rates are equal:

$$k_f[A]^a[B]^b = k_r[C]^c[D]^d. \quad (4)$$

Rearranging

$$K_{eq}^c = \frac{k_f}{k_r} = \frac{[C]^c[D]^d}{[A]^a[B]^b} \quad (5)$$

in which K_{eq}^c is the conditional equilibrium constant based on species concentrations.

Free-energy definition

The chemical potential of any species in solution (μ_i) is given as:

$$\mu_i = \mu_i^0 + RT \ln(i) \quad (6)$$

in which μ_i^0 is the standard chemical potential of species i , R is the ideal gas constant, T is the temperature in Kelvin, and (i) is the activity of species i . The expression for the free-energy change of any chemical reaction is:

$$\Delta G = \sum v_i \mu_i \quad (7)$$

in which ΔG is the change in Gibbs free energy during the course of the reaction, and v_i is the stoichiometric coefficient for the components of the equilibrium expression (v_i is positive for products, negative for reactants). Substituting:

$$\Delta G = \sum_i v_i \mu_i^0 + RT \sum_i v_i \ln(i) \quad (8)$$

or

$$\Delta G = \Delta G^0 + RT \ln \prod_i (i)^{v_i} \quad (9)$$

and ΔG^0 is the standard Gibbs free energy change of the reaction. The reaction quotient, Q , can be represented by:

$$Q = \ln \prod_i (i)^{v_i}, \quad (10)$$

such that:

$$\Delta G = \Delta G^0 + RT \ln Q. \quad (11)$$

By definition, the free-energy change of reaction equals zero ($\Delta G = 0$) at equilibrium, and the value of Q at equilibrium becomes the equilibrium constant, K_{eq}^0 :

$$K_{eq}^0 = Q_{eq} = \prod_i (i)_{eq}^{v_i} \quad (12)$$

and:

$$\Delta G^0 = -RT \ln K_{eq}^0. \quad (13)$$

Thus, we have the free-energy definition of equilibrium and the thermodynamic derivation of the equilibrium constant in which K_{eq}^0 is the equilibrium constant based on activities of the species. The expression for the K_{eq}^0 for the generalized equilibrium (Eq. 1) is given by

$$K_{eq}^0 = \frac{(C)^c (D)^d}{(A)^a (B)^b} \quad (14)$$

where the activity of species X is defined as $(X) = \gamma_x [X]$ and γ_x is the activity of species X . Substituting into Eq. (5),

$$K_{eq}^0 = \frac{\gamma_c [C]^c \gamma_d [D]^d}{\gamma_a [A]^a \gamma_b [B]^b} = K_{eq}^c \frac{\gamma_c \gamma_d}{\gamma_a \gamma_b}. \quad (15)$$

Le Chatelier's principle and chemical equilibrium in soils

Le Chatelier's principle is a fundamental concept that predicts the impact of change on chemical equilibria. Le Chatelier's original work is still available (Le Chatelier, 1884) and can be paraphrased:

If a system at equilibrium receives a stress (change in pressure, volume concentration, temperature), then the equilibrium will be disrupted. The system will experience internal modifications that will induce changes that are opposite in sign to that of the stress, resulting in a relief of that stress and, ultimately, a new state of equilibrium.

Referring to the generalized chemical equilibrium (Eq. 1):

if one of the products, D , is added to the system to increase the concentration of D , then according to Le Chatelier's principle, the equilibrium would shift to the left to reduce the concentration of D to "relieve the stress." Product D will react with product C , decreasing both D and C , and increasing the concentrations of A and B until a new equilibrium is reached. In the context of free energy, adding D to the system induces an initial change in free energy such that $\Delta G \neq 0$ and $Q \neq K_{eq}^0$. Concentrations will change until the inequalities are removed: $\Delta G = 0$ and $Q = K_{eq}^0$. From a kinetics perspective, increasing the concentration of D will increase v_r , and $v_f \neq v_r$. Rates of consumption of C and D will increase as will the rate of production of A and B . Eventually, the forward and reverse reactions will begin to balance until $v_f = v_r$ once more.

Applicability of chemical equilibrium principles to soils

Invoking the assumption of chemical equilibrium in soils, particularly under natural conditions, is difficult because soils are highly complex and forever changing. Soils continually have inputs of external energy, water, gases, and dissolved constituents. Losses of these same components are equally possible through the radiation of heat, leaching, and biological activities. These changes perturb the soil system and upset any equilibrium that may be present. With this in mind, a reasonable question is, “Can the principles of chemical equilibrium be applied to soils?”

Despite the dynamic nature of soils and continuous inputs and removal from the system, chemical equilibrium can be applied if care is taken, the limitations are clearly understood, and expectations are reasonable.

Limitations to equilibrium in soils

Most soils are open systems with frequent inputs and removal of mass and energy. Even the simple act of rain falling on a soil results in the dilution of dissolved constituents and disruption of previous equilibria. Changes in temperature, plant assimilation of nutrients, evaporation of water, and diffusion of gases into or out of soil have a similar disruptive effect. These perturbations in equilibrium may be temporary or may have long-term implications, depending upon the kinetics of these reactions. In aqueous solutions, reactions tend to establish equilibrium relatively quickly. For example, the half-life of complexation and dissociation reactions varies from 10^{-8} to 10^4 s (Table 1). Thus, outside disturbances to equilibria will have a small impact on most complexation reactions. The slowest reaction in Table 1 is the oxidation of Fe(II) to Fe(III) at pH 6, with a half-life of approximately 3 h.

Solid-phase dissolution and precipitation reactions can require a long time to achieve equilibrium relative to aqueous phase complexes. A classic example of this is the precipitation and dissolution of gibbsite (γ -Al(OH)₃) which has been studied frequently. The chemistry of aluminum in soils is complex, in both the solution and solid phases. Nevertheless, apparent chemical equilibrium with gibbsite has been observed. Fig. 1 illustrates the time trend as an acidic solution of 0.025 mol L^{-1} Al was slowly leached

Table 1 Reaction orders and half-lives of selected complexation and dissociation reactions in aqueous solutions. All data from Pankow and Morgan (1981) unless otherwise stated.

Reaction	Order	Half-life (s)
$\text{MnSO}_4(\text{aq}) \leftrightarrow \text{Mn}^{2+} + \text{SO}_4^{2-}$	1	10^{-8}
$\text{H}^+ + \text{HS}^- \leftrightarrow \text{H}_2\text{S}$	2	10^{-8}
$\text{FeOH}^{2+} + \text{H}^+ \leftrightarrow \text{Fe}^{3+} + 3\text{H}_2\text{O}$	2	10^{-8}
$\text{Fe}^{3+} + 3\text{H}_2\text{O} \leftrightarrow \text{FeOH}^{2+} + \text{H}^+$	1	10^{-7}
$\text{Mn}^{2+} + \text{SO}_4^{2-} \leftrightarrow \text{MnSO}_4(\text{aq})$	2	10^{-6}
$\text{Cr}^{3+} + \text{H}_2\text{O} \leftrightarrow \text{CrOH}^{2+} + \text{H}^+$	1	10^{-6}
$\text{FeOH}^{2+} + \text{H}_2\text{O} \leftrightarrow \text{Fe(OH)}_2^+ + \text{H}^+$	1	10^{-5}
$\text{H}_2\text{S} \leftrightarrow \text{H}^+ + \text{HS}^-$	1	10^{-4}
$\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3$	1	10^1
$\text{CO}_2 + \text{OH}^- \leftrightarrow \text{HCO}_3^-$	2	10^{-1}
$\text{Fe}^{2+} + \text{O}_2 \leftrightarrow \text{Fe(III)} \text{ (pH 8)}$	2	10^0
$\text{Fe}^{2+} + \text{O}_2 \leftrightarrow \text{Fe(III)} \text{ (pH 7)}$	2	10^2
$\text{Fe}^{3+} + \text{F}^- \leftrightarrow \text{FeF}^{2+}$	2	10^{2a}
$\text{Fe}^{2+} + \text{O}_2 \leftrightarrow \text{Fe(III)} \text{ (pH 6)}$	2	10^4

^aPlankey and Patterson (1986).

Fig. 1 The approach to equilibrium with gibbsite over time for soluble Al in two soils. In this case, $K_{\text{SP}} = (\text{Al}^{3+})(\text{OH}^-)^3$. The dashed line represents equilibrium with γ -Al(OH)₃(gibbsite). Data from Marion et al. (1976).

through soils (Marion et al., 1976). Equilibrium was approached from supersaturated conditions, with aluminum solids precipitating as the solution passed through the soils. In the Anthony soil (entisol from Arizona), equilibrium with gibbsite was approached in approximately 10 days. The exudate solution from the Molokai soil (oxisol from Hawaii) was still 10 times above gibbsite saturation at 10 days and did not approach apparent equilibrium until 40 days. Slight shifts in pH, temperature, or moisture content would result in nonequilibrium conditions for $\gamma\text{-Al(OH)}_3$ (gibbsite) that would again require several days to correct.

Some reactions are thermodynamically favorable but are associated with a large energy barrier (e.g., energy of activation). Unless that energy barrier can be overcome, equilibrium will not be realized. The conversion of $\text{N}_2(\text{g})$ to nitrate should be a spontaneous reaction, but the presence of approximately 78% $\text{N}_2(\text{g})$ in the atmosphere is clear evidence that this reaction does not proceed as predicted. Redox couples with oxygen-containing anions (e.g., arsenite/arsenate ($\text{AsO}_3^{3-}/\text{AsO}_4^{3-}$)) also attain equilibrium slowly in the absence of a catalyst.

Measurement of critical system variables can be subject to limitations that restrict rigorous application of thermodynamics to natural soils. Detection limits of soluble constituents may preclude quantification, redox-sensitive electrodes have shortcomings, and distinguishing oxidation states of soluble elements can be troublesome. Redox is a crucial system parameter, but chemical limitations of redox electrodes are well documented. Not all oxidation–reduction couples establish reversible equilibria at the surface of the sensing electrode.

Thermodynamic data and/or equilibrium constants are available for hundreds of minerals found in soils, but many of these minerals can only be formed under conditions of high temperatures and pressures. This is particularly true of the primary minerals in soils. The chemical reaction can be written, and thermodynamics might predict that these minerals form in soils. However, considerations of equilibrium have less impact when one or more of the constituents cannot form.

Organic solid phases and soluble organic matter participate in soil chemical reactions, and equilibrium can be established. However, organic compounds in soils can be dynamic and transform relatively rapidly. Many elements in soil react strongly with organic matter, including Fe (iron), Al, Cu (copper), Zn (zinc), As (arsenic), and P (phosphorus). These interactions are difficult to predict because of the structural, temporal, and spatial variability of soil organic matter but should not be ignored when assessing the equilibrium status of soils.

Soil systems in which equilibrium concepts may apply

Chemical equilibrium principles can be applied with reasonable confidence to most reactions occurring exclusively in the solution phase. As illustrated in Table 1, most reactions attain equilibrium in a few seconds or less; therefore, typical perturbations to equilibrium relax quickly for these soluble components. Attempts to apply equilibrium to the solid phase in the soil require more consideration. The kinetics of dissolution of typical soil minerals are slow. Calcium phosphate and calcium sulfate minerals can achieve equilibrium in hours; aluminum phosphates, carbonates, and most oxides in a matter of days or weeks; and complex aluminosilicates in years. If the soil solution has been in contact with soil minerals for the time necessary to establish equilibrium while experiencing minimal disturbances, application of equilibrium principles is theoretically possible. Complete equilibrium among all species in the soil solution and all soil minerals is not essential; however, these principles cannot be applied with confidence if even one component ion of the mineral being studied is out of equilibrium.

Consider the example of variscite, $\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$. Phosphate ions may reach constant concentrations in a matter of hours in the soil solution, but Al^{3+} may require days or weeks due to the slow reaction kinetics of aluminum oxides. Therefore, the system will be in equilibrium only when both Al^{3+} and PO_4^{3-} have reached time-independent concentrations.

Universal adherence to chemical equilibrium in soils is unrealistic. However, employing thermodynamics and associated solubility and complexation constants in soil systems can be fruitful if one has reasonable expectations.

Predict endpoints of reactions Thermodynamics can be useful in determining possible endpoints versus impossible outcomes of chemical reactions in soils. For example, we can predict that metallic iron will readily convert to ferric oxides under surface soil conditions:

but the reverse reaction would be highly unfavorable.

Determine ionic activities in soil solution The activities of individual species in the soil solution are often the driving forces behind many chemical and biological reactions in soils and can be calculated using chemical equilibrium constants.

Calculate final conditions for systems that attain equilibrium rapidly When changes to the soil system occur infrequently relative to the timescale required for equilibrium, then equilibrium concepts can be applied.

Experimental approach to equilibrium in soils

Thermodynamics may be used to describe chemical reactions in soils, interpret experimental data, or predict changes in soil chemistry induced by environmental perturbations. In all cases, the user must be aware of the limitations of chemical equilibrium in soils and must have knowledge of the systems to which these principles may be applied. The steps taken are generally the same: critical system variables must be identified; key reactions of all the contributing and interacting components are established; reliable equilibrium constants are located and assigned to each reaction; and, finally, the system of equilibrium equations is set up as a mathematical array and solved.

System variables

The most important variables in a soil system are similar to those in any other geochemical environment. The list of parameters to be considered is driven in part by the interest and focus of the user and is strongly influenced by other variables that are intimately linked to the systems of interest. For example, if one is considering only the solubility of aluminum oxides in soils with low pH, then the obvious system parameters are pH and soluble Al. However, Al^{3+} can form important solution complexes with Cl^- (chloride), SO_4^{2-} (sulfate), and F^- (fluoride). Therefore, one must account for these ancillary anions before the Al system can be fully defined.

Reactions and associated equilibrium constants

For any given system, all relevant reactions and the corresponding constants must be identified. This is an arduous task and requires databases of reliable information. Much of this work was done in the development of geochemical models, as will be discussed below. For a very simple system such as $\gamma\text{-Al}(\text{OH})_3$ (gibbsite) in equilibrium in soil, the following solution species should be considered: Al^{3+} , AlF^{2+} , AlF_2^+ , AlSO_4^+ , AlOH^{2+} , $\text{Al}(\text{OH})_2^+$, and $\text{Al}(\text{OH})_3^\circ$. Other complexes that could be important include polynuclear Al species, $\text{Al}_x(\text{OH})_y(\text{H}_2\text{O})_z$ (Bertsch and Parker, 1995) and soluble organic complexes (Nordstrom and May, 1995). A typical equation and constant would be:

for which $\log K_{\text{eq}}^\circ = -5.00$. Equations and constants are assembled for all species, including the dissolution reaction for the controlling solid phase:

and $\log K_{\text{eq}}^\circ = 7.74$. After all species have been associated with an independent equation or an actual measurement of a system parameter (e.g., total soluble Fe or pH), they are assembled in a mathematical array of simultaneous equations; the array is solved, and the system can be defined exactly. For small systems, this can be done by hand, but larger systems require a full geochemical model to provide a solution.

Equilibrium modeling of soil systems

Solving the array of simultaneous equations that results from defining a soil system in equilibrium provides a serious challenge. Hand solutions are time-consuming as is writing small computer programs for each new system. Fortunately, this problem was recognized in the mid-1970s, and several research groups set about the task of writing generalized computer models for geochemical systems.

Geochemical models Perhaps the earliest published computer-based geochemical model was designed to map the reaction pathways involving minerals and aqueous solutions (Helgeson, 1968). The WATEQ model was a relatively comprehensive one with a carefully reviewed database of thermodynamic constants (Truesdell and Jones, 1974). The MINEQL model was designed for rapid execution times with the ability for ‘mass transfer’, quantitatively transferring constituents into and out of the solid phase as required by equilibrium constraints (Westall et al., 1976). Since the early beginnings, geochemical modeling has evolved in many directions with many new models: GEOCHEM; PHREEQC; SOILCHEM; visual MINTEQ; GEMS-PSI; Geochemist’s Workbench; and many others. Some models have transport features, and others build in graphic capabilities for visualizing results.

Model inputs Each model requires that the user define the systems under consideration. The computer models can accept experimental data for calculating ionic activities and comparing them with mineral solubilities. The models also may be used in a predictive mode in which assumptions are made concerning equilibrium with solid phases, pH, temperature, gas partial pressures, etc. The models then will report resulting activities, total elemental solubilities, residual masses of solid phases, and the distribution of mass of a given element across all phases.

Continuing with the aluminum example, let us assume equilibrium with $\gamma\text{-Al}(\text{OH})_3$ (gibbsite) at pH 6.5 of pH 5 with total soluble fluoride of $2.0 \times 10^{-5} \text{ mol L}^{-1}$, and total soluble sulfate 0.001 mol L^{-1} . This information was used as input for the visual MINTEQ model (Gustafsson, 2022), and the results are given in Table 2. Total Al solubility is strongly affected by pH as is the distribution of soluble species. Although polynuclear Al species are known to be important in aqueous systems, the modeling results predict that these species will account for $<<1\%$ of soluble Al, agreeing with the notion that these species are metastable (Bertsch and Parker, 1995).

Application of chemical equilibrium to soils: Examples

This section will explore several instances of the application of equilibrium to soils in which soil solution measurements were used as inputs into a geochemical model. The output of the model was then used to determine the ion activity products (IAP) and to compare them with corresponding equilibrium constants. The first examples will illustrate apparent equilibrium followed by apparent nonequilibrium examples.

Table 2 Modeling results with visual MINTEQ with imposed gibbsite equilibrium, total SO_4^{2-} 0.001 mol L^{-1} , total F $2.00 \times 10^{-5} \text{ mol L}^{-1}$, and either pH 6.5 or pH 5.

Component	Species	pH 6.5		pH 5	
		log (activity)	% of total	log (activity)	% of total
SO_4^{2-}	SO_4^{2-}	-3.10	100	-3.10	99.9
F	F	-4.27	99.9	-5.33	24.7
	HF°	-8.04	<0.1	-7.15	0.4
	AlF^{2+}	-9.47	<0.1	-5.58	16.4
	AlF_2^+	-8.58	<0.1	-5.29	54.3
Al^{3+}	AlF_3°	-9.23	<0.1	-6.55	4.2
	Al^{3+}	-11.76	<0.1	-7.26	0.9
	AlOH^{2+}	-10.26	0.9	-7.26	0.7
	Al(OH)_2^+	-9.05	11.9	-7.55	0.3
	Al(OH)_3°	-8.95	14.4	-8.95	<1
	Al(OH)_4^-	-8.76	23.6	-10.26	<1
	AlSO_4^+	-11.02	0.1	-6.52	3.4
	AlF^{2+}	-9.47	5.4	-5.58	34.5
	AlF_2^+	-8.58	36.0	-5.29	57.0
	AlF_3°	-9.23	7.6	-6.55	3.0
	Soluble Al ^a	-8.11	100.0	-5.02	100

^aSoluble Al is the sum of the concentrations of all aqueous Al species in mol L^{-1} .

Interactions of lead and phosphate in contaminated soils

Soils contaminated with lead (Pb) can be amended with soluble phosphate to reduce the environmental and health risks of Pb. The reaction between Pb^{2+} and PO_4^{3-} can result in the formation of sparingly soluble minerals such as hydroxyphosphomorphite ($\text{Pb}_5(\text{PO}_4)_3\text{OH}$). A contaminated soil was treated with combinations of CaCO_3 (calcite), rock phosphate, or potassium phosphate; aged for approximately 70 days; and samples of the soils were suspended in water for 7 days (Zwonitzer et al., 2003). Soluble constituents were measured, and activities were determined with a geochemical model. Despite the relatively short equilibration times, correspondence between the measured activities and theoretical solubility suggests equilibrium with hydroxyphosphomorphite for those soils amended with KH_2PO_4 (with or without CaCO_3) and for soils amended with rock phosphate without CaCO_3 (Fig. 2). The soils treated with CaCO_3 only, rock phosphate plus CaCO_3 , and the untreated control soil were apparently in equilibrium with PbCO_3 (cerussite). Those soils amended with rock phosphate only may have been in simultaneous equilibrium with cerussite and hydroxyphosphomorphite.

Fig. 2 The impact of fertilization of Pb-contaminated soil in apparent equilibrium with PbCO_3 (cerussite) or $\text{Pb}_5(\text{PO}_4)_3\text{OH}$ (hydroxyphosphomorphite). Soil suspensions were equilibrated for 5 days (Zwonitzer et al., 2003).

Manganese(III) phosphate

Manganese is a critical element in soils for plant and animal nutrition but can be a pollutant if Mn concentrations become elevated. Manganese phosphates are known to form in natural environments but are too soluble to persist, with the exception of Mn(III) $\text{PO}_4 \cdot 1.5\text{H}_2\text{O}$. Although the equilibrium constant for this mineral ($\log K_{\text{eq}}^0 = -34.4$) suggests very low solubilities, Mn(III) is present in vanishingly small concentrations in soil ($10^{-15} \text{ mol L}^{-1}$ as Mn^{3+}). Nevertheless, two studies seem to suggest that the mineral can form in P-fertilized soils (Boyle and Lindsay, 1985; Schwab, 1989).

Activities of PO_4^{3-} and Mn^{3+} were determined in calcareous soils (Boyle and Lindsay, 1985), and the correspondence between these activities and the theoretical solubility of $\text{Mn(III)PO}_4 \cdot 1.5\text{H}_2\text{O}$ was apparent (Fig. 3). A similar study was conducted in nonalkaline soils (Schwab, 1989), and two trends were observed in solubility, depending upon whether the soil had been recently fertilized. In soils fertilized annually with soluble phosphate, activities were slightly elevated relative to $\text{Mn(III)PO}_4 \cdot 1.5\text{H}_2\text{O}$, suggesting the presence of a less-crystalline, more soluble form of the mineral. However, in those soils in which P applications had ceased several years prior to soil sampling, the correspondence between measured and theoretical activities for $\text{Mn(III)PO}_4 \cdot 1.5\text{H}_2\text{O}$ was closer. A gradual approach to solid-phase equilibrium is expected in all soils (Fig. 1), and apparent steady state with a more soluble variant of a solid phase is observed frequently.

Calcite in soils: Equilibrium, nonequilibrium, supersaturation

Precipitation in soils of calcium carbonate, presumed to be calcite, is considered easily reversible and quickly establishes equilibrium. Although many studies examining this mineral have been conducted and support the notion of calcite equilibrium, others have found varying degrees of nonequilibrium. When at equilibrium, the solubility of calcite may be expressed by the following equation:

for which $\log K_{\text{eq}}^0 = -8.48$. Determining the single ion activities of Ca^{2+} and CO_3^{2-} in soil solution makes possible the comparison of measured IAP to the thermodynamic constant. Theoretically, if care is taken in determining the ionic activities, then correspondence between measured and predicted activities can be observed. A series of experiments were run to determine the time needed to reach equilibrium and the state of calcite saturation in groundwaters and calcareous soils (Suarez et al., 1992; Amrhein et al., 1993). Soil solutions were equilibrated for up to 20 days, and activities were determined by various methods. Both the groundwater and soil solutions were found to be in apparent supersaturation with respect to calcite (Fig. 4). The cause of the supersaturation appeared to be the dynamic nature of the soils in which organic matter mineralized rapidly enough to maintain slightly elevated ion activity products for Ca^{2+} and CO_3^{2-} relative to the thermodynamic solubility constant. For soil, the $\log \text{IAP} = -8.2$ was slightly supersaturated compared to $\log K_{\text{eq}}^0 = -8.48$. For groundwater, $\log \text{IAP} = -8.01$. In another study of subsoils with higher pH, the result was similar ($\log \text{IAP} = -8.2$) suggesting that achieving a steady state with elevated Ca^{2+} and CO_3^{2-} activities is a common occurrence. Determining whether this is a function of continual generation of ions from organic matter or the formation of a transient solid phase with greater solubility would need to be determined in each case.

The outlook for studying chemical equilibrium in soils

Advances in geochemical modeling and computing capacity have established new approaches to studying soils. Many applications are possible and include plant nutrition, fate of fertilizers, leaching of soluble constituents, examining the mobility of contaminant

Fig. 3 Comparison of Mn^{3+} and PO_4^{3-} activities to $\text{MnPO}_4 \cdot 1.5\text{H}_2\text{O}$ solubility. Activities were calculated from experimentally determined solution parameters (Boyle and Lindsay, 1985; Schwab, 1989).

Fig. 4 Measured Ca^{2+} and CO_3^{2-} activities in field soil solutions (open squares; Suarez et al., 1992), groundwater samples (filled circles; Suarez et al., 1992), and saturated extracts from soils (open triangles; Visconti et al., 2010). The solid line is the theoretical solubility of CaCO_3 (calcite) ($\log K_{\text{sp}} = -8.48$). The dashed lines correspond to regression equations for the groundwater samples ($\log \text{IAP} = -8.01$) and the combined soil samples from Suarez et al. (1992) and Visconti et al. (2010) ($\log \text{IAP} = -8.20$). Solution concentration data were used to calculate activities with visual MINTEQ (Gustaffson, 2022).

metals, and volatilization of organics from soils. Examples can be found in the literature that illustrate the relevance of chemical equilibrium in living, dynamic systems.

The DTPA soil test for micronutrients was developed by relating mechanisms of plant uptake to soil chemical equilibrium principles (Lindsay and Norvell, 1978). A mathematical simulation of soil solid phases in the presence of the chelate, DTPA, maximized the correlation between extractable concentrations and phytoavailability of Zn, Mn, Fe, and Cu. The method has been cited thousands of times and is used internationally.

To offset ever dwindling supplies of high-quality phosphate rock used in the production of P fertilizers, efforts are being made to recover phosphate from waste streams. Geochemical modeling demonstrated that struvite ($\text{NH}_4\text{MgPO}_4 \cdot 6\text{H}_2\text{O}$) can be produced and recovered from sludge, and geochemical modeling was employed to optimize the process (Daneshgar et al., 2019; Morita et al., 2019).

Complex cement materials have been modeled thermodynamically to provide a better understanding of the basic reactions in the formation of cement and to avoid unwanted side reactions (Kulik et al., 2021). With this approach, the potential for magnesium phosphates to act as cements was demonstrated (Lothenbach et al., 2019). Chemical equilibrium modeling explained how acid treatments degrade smectite clays and prevent the formation of ettringite in soil cements (Akula et al., 2020).

Human and environmental risk assessments nearly always include knowledge of water-soluble concentrations for pollutants of interest. Integrating geochemical modeling into the assessment can provide concentrations of specific toxic species (e.g., CrO_4^{2-} vs Cr^{3+}) or predict changes in risk in response to contamination or pollutant abatement measures. In Pakistan and Thailand, deep aquifers (>30 m depth) were found to exceed regulatory limits for arsenic in drinking water, and geochemical modeling indicated that Fe-oxides may be responsible for the excessive arsenic concentrations (Shakoor et al., 2018; Santha et al., 2022). Geochemical modeling was interfaced directly with risk assessment models by providing concentrations of the Cd^{2+} species, assumed to be the toxic agent in high Cd groundwater (Miao et al., 2021).

Powerful geochemical models and knowledge of the chemical and physical limitations of applying chemical equilibria in soils can prepare soil scientists to tackle the most challenging and interesting problems of chemical behavior in soil systems.

Abstract

The dissolution and precipitation of minerals control the physical properties and chemical composition of soil, speciation and reactivity of contaminants, and preservation of soil organic matter. In this chapter, the basic theories of mineral dissolution and precipitation are first introduced conceptually. Then the biotic and abiotic mineral dissolution processes and the formation and transformation processes of the precipitated soil minerals are discussed with examples of common soil minerals. Lastly, the environmental significance of soil mineral dissolution and precipitation is addressed from the perspective of the sequestration of heavy metals and soil organic matter.

Key points

The objectives of this chapter are:

- To describe briefly the basic theories for dissolution and precipitation of soil minerals;
- To review both abiotic and biotic dissolution of typical soil minerals including aluminosilicates, metal-oxides, and sulfides;
- To review the precipitation and transformation mechanisms of minerals in the soil environment;
- To demonstrate the effects of soil mineral dissolution and precipitation processes on the sequestration of heavy metals and soil organic matter.

Introduction

Soil is the top layer of the Earth's crust which is composed of soil minerals, soil organic matter (SOM), and soil animals and microbes. Originally, the rocks break down during a long period of time by various physical, chemical, and biological processes, which is commonly called weathering. The fine particles after weathering aggregate together and form the physical structure of soil. Natural rainfall and wind erode and transport soil particles, often causing the further decrease of their particle size. The soil contains the remains of dead plants and animals, which gradually forms SOM, together with the input from soil microbes. The mineral nutrients present in the soil are determined by the parent material from which the soil has formed from. The abovementioned soil formation (pedogenic) processes make the soil porous and aerated, and as a result the quality of the soil and the soil structure is improved.

During pedogenic processes, the dissolution of primary minerals and the precipitation of secondary minerals often play a critical role. The primary minerals that are less resistance to chemical weathering (i.e., calcite, olivine) can be preferentially dissolved by the carbonic acid from rainfall or the organic acids and acidic substances derived from the decomposition of organic matter in soil, while other less soluble minerals (quartz, micas, and some feldspars) can persist in soil for a long period of time. Some of the dissolved ions can reprecipitate and crystallize to secondary minerals through chemical processes including hydrolysis and oxidation. Among the many soil minerals, clay and Fe (iron), Al (aluminium), and Mn (manganese) (hydr)oxides are the most reactive ones because of their large specific surface areas and abundant surface functional groups. These minerals assist in the preservation of SOM

and provide a habitat for microbial reproduction. On the other hand, soil minerals interact with soil organic or inorganic contaminants and affect the environmental behavior of soil pollutants. Overall, the dissolution and precipitation of minerals are significant (bio)geochemical processes in soil, which can have a remarkable influence on the fate of elements and pollutants.

Theories for dissolution and precipitation of soil minerals

In general, the dissolution and precipitation of soil minerals can be considered as reversible reactions,

where M represents the mineral phase that composes of soluble components A_i , and s_i represents the stoichiometric coefficient of soluble component A_i .

In chemical thermodynamics, saturation index (SI) is an indicator for the direction of dissolution and precipitation reactions,

$$SI = \log_{10} \left(\frac{IAP}{K_{sp}} \right) \quad (2)$$

$$K_{sp} = \prod_i a_{eq,A_i}^{s_i} \quad (3)$$

$$IAP = \prod_i a_{A_i}^{s_i} \quad (4)$$

In above equations, IAP is the ion activation product of dissolved ions in the aqueous phase, K_{sp} is the solubility product of the mineral phase, a_{eq,A_i} which represents the activity of solute species A_i under dissolution–precipitation equilibrium, and a_{A_i} represents the activity of the same solute in the solutions for calculating SI. When $SI > 0$, the aqueous phase is over-saturated, and the ions may precipitate to approach the equilibrium status. When $SI < 0$, the aqueous phase is undersaturated and the mineral phase may dissolve and release the soluble ions to increase the IAP, until chemical equilibrium is reached. The minerals in soil include a variety of primary and secondary minerals such as quartz, ferrihydrite, hematite, goethite, gibbsite, calcite, dolomite, siderite, gypsum, sulfates, etc. An important measure that describes mineral solubility is pK_{sp} (the negative logarithm of mineral solubility K_{sp}) ($pK_{sp} = -\log_{10} K_{sp}$). Table 1 give the pK_{sp} values of some common minerals (Ball and Nordstrom, 1991).

Although the direction of mineral dissolution–precipitation reactions can be determined from the thermodynamic index SI, the rates of reactions are related to the properties of mineral surfaces in addition to the saturation states of the aqueous phase. The transition-state-theory (TST)-based rate is a widely used theoretical model that can correlate the rates of mineral dissolution with the factors mentioned above. A simplified form of TST-based rate can be expressed as,

$$R = Ak \left(1 - e^{-\frac{n\Delta G}{R_g T}} \right) = Ak \left(1 - \left(\frac{IAP}{K_{sp}} \right)^n \right) \quad (5)$$

where R represents the rate of reaction, A is the reactive surface area of the dissolving mineral, k is the intrinsic dissolution rate constant for the given reaction, ΔG is the free energy change of the dissolution reaction, R_g is the gas constant, T is the absolute temperature, and n is the constant related to the reaction. If we assume $n = 1$ (has been widely applied in dissolution–precipitation of several minerals, i.e., quartz and calcite), the term $\left(1 - \frac{IAP}{K_{sp}} \right)$ represents the degree of disequilibrium for the aqueous phase solutes, which is considered to be the thermodynamic driving force of mineral dissolution.

Mineral dissolution may involve different reaction mechanisms such as proton-promoted dissolution, ligand-promoted dissolution, reductive dissolution, and so on. In some complicated conditions, several parallel reaction pathways may simultaneously determine the kinetics of mineral dissolution. For example, calcite dissolution has three parallel pathways as shown in following equations,

In this case, the overall rate of reaction of calcite dissolution is the sum of the rates for the three parallel reactions,

$$R = A(k_1 a_{H^+} + k_2 a_{H_2CO_3} + k_3) \left(1 - \frac{IAP}{K_{sp}} \right) \quad (9)$$

where a_{H^+} and $a_{H_2CO_3}$ are the activities of H^+ and H_2CO_3 in the aqueous phase, respectively, and k_1 , k_2 and k_3 represent the intrinsic rate constants of reactions (6), (7) and (8), respectively.

The rate limiting steps in mineral dissolution may vary in different environmental conditions. There are three typical rate-limiting steps including transport control, surface reaction control, and mixed transport and surface reaction control. Fig. 1

Table 1 The pK_{sp} values of some common minerals.

Mineral	pK_{sp}	Formula
Al(OH) ₃ (a)	31.17	Al(OH) ₃
Gibbsite	33.86	Al(OH) ₃
Boehmite	33.39	AlOOH
Diaspore	35.09	AlOOH
Witherite	8.56	BaCO ₃
Barite	9.97	BaSO ₄
Portlandite	5.18	Ca(OH) ₂
Hydroxyapatite	54.45	Ca ₅ (PO ₄) ₃ OH
Aragonite	8.34	CaCO ₃
Calcite	8.48	CaCO ₃
Dolomite	17.09	CaMg(CO ₃) ₂
Anhydrite	4.36	CaSO ₄
Fe(OH) ₃ (a)	37.08	Fe(OH) ₃
Hematite	87.95	Fe ₂ O ₃
Magnetite	108.18	Fe ₃ O ₄
Greigite	101.00	Fe ₃ S ₄
Greenalite	63.13	Fe ₃ Si ₂ O ₅ (OH) ₄
Siderite	10.89	FeCO ₃
Mackinawite	18.64	FeS
Pyrite	26.89	FeS ₂
Jarosite(ss)	90.35	K _{0.77} Na _{0.03} H _{0.2} Fe ₃ (SO ₄) ₂ (OH) ₆
Brucite	11.14	Mg(OH) ₂
Magnesite	8.03	MgCO ₃
Rhodochrosite(d)	10.39	MnCO ₃
Birnessite	15.62	MnO ₂
Pyrolusite	17.84	MnO ₂
Manganite	18.26	MnOOH
Quartz	3.98	SiO ₂
SiO ₂ (a)	2.71	SiO ₂

Fig. 1 Schematic representation of concentration in solution, C , as a function of distance from the surfaces of the dissolving mineral (A, B) and reaction time (C, D) for (A, C) transport-controlled and (B, D) surface reaction-controlled dissolution processes. Reproduced with permission from Stumm W (1992) *Chemistry of the Solid-Water Interface: Processes at the Mineral-Water and Particle-Water Interface in Natural Systems*. John Wiley & Son Inc.

shows different concentration profiles of dissolved ions as a function of distance from the surfaces of dissolving minerals for both transport and surface reaction-controlled dissolution (Stumm, 1992). For the transport-controlled dissolution process, the overall rates of reaction are mainly limited by the physical transport of dissolved products from the mineral surfaces to the bulk solution. As a result, the concentrations of dissolved products decay slowly with distance from the mineral surfaces. In comparison, for the surface reaction-controlled dissolution process, there is no limit to the transport of dissolved products and their concentrations close to the mineral surfaces are almost the same as that in the bulk solution. These two systems also result in different concentration profiles as a function of reaction time as shown in Fig. 1. In certain conditions, a mixed transport and surface reaction-controlled dissolution may develop, and the concentrations profile will vary between the above two scenarios.

The kinetics of mineral precipitation are usually complicated because of the multi-step reaction mechanisms. To form the precipitates, the supersaturated ions in the aqueous phase need to nucleate first and the morphology of precipitate is highly dependent on the degree of solution supersaturation. The small nuclei then gradually grow to larger particles accompanied by the consumption of supersaturated solute ions (decreasing IAP). With greater aqueous phase supersaturation, the solid phase can nucleate with a larger number and finer size of nuclei. At the crystal growth stage, a large number of nuclei can further limit the size of particles and make the precipitates more dispersed or poorly crystallized. After the supersaturation has been fully depleted ($SI \leq 0$), the morphology of the poorly crystallized minerals may change further through the Ostwald ripening mechanism or recrystallize to form the chemically more stable mineral phases. Therefore, the precipitated minerals may vary in morphology and crystal structure depending on the stepwise kinetic behavior of nucleation, crystal growth, and Ostwald ripening and recrystallization. The comprehensive review by Fritz and Noguera (2009) provides detailed information on the theoretical background of the kinetics for mineral precipitation.

Abiotic dissolution of minerals

Silicate or aluminosilicate minerals usually have slow rates of dissolution and a lifetime over many years, but they may eventually dissolve in typical soil environments. During the dissolution processes, both congruent and incongruent pathways may occur. In congruent dissolution, the dissolution of a mineral produces only soluble species, such that the stoichiometry of components in the mineral and solution phases after equilibrium are identical, while in the incongruent pathway, the dissolution of a mineral produces one or more mineral species. Feldspar is an abundant mineral component in soils derived from granites and their parent materials, and its incongruent dissolution can release nutrient elements such as K (potassium), Na (sodium), Ca (calcium), and Si (silicon) to the ecosystem, and promotes the long-term alteration of soil mineral composition. The albite (also known as sodium-feldspar) dissolution process is often accompanied by the precipitation of secondary clay minerals, such as kaolinite. The overall reaction can be expressed simply as Eq. (10),

When the albite is dissolved, Na^+ ions and silicic acid only are released into the aqueous phase while Al is enriched in the newly precipitated clay mineral (kaolinite). Because the dissolution of feldspar in typical soil environmental conditions is known to be very slow, the rate of reaction is more likely to be controlled by the surface reactions rather than the transport processes (Fig. 1).

In general, the dissolution kinetics of silicate, aluminosilicate and other oxide type minerals depends strongly on the solution pH (Chou and Wollast, 1985). Fig. 2 shows that the rates of dissolution for albite are the lowest in the neutral pH range and much higher under both acid or basic conditions.

Dissolution of oxide-type minerals is catalyzed by H^+ or OH^- which results from producing the charged surface complexes (Eqs. 11 and 12) that can polarize and weaken the metal(loid)-oxygen binding with the underlying crystal lattice (Stumm, 1992; Brantley, 2008).

With increasing concentrations of charged surface complexes of SiOH_2^+ under low pH or SiO^- under high pH, the surface reaction-controlled dissolution rates increase. Moreover, the uncharged surface sites also dissolve simultaneously without the catalytic contribution of H^+ and OH^- , and contribute to the dissolution kinetics under neutral conditions. Therefore, the pH dependent dissolution rates of silicate can be calculated quantitatively as follows,

$$R = A(k_{\text{acid}}a_{\text{H}^+}^{n_{\text{H}^+}} + k_{\text{neutral}} + k_{\text{base}}a_{\text{OH}^-}^{n_{\text{OH}^-}}), \quad (13)$$

where k_{acid} , k_{neutral} , and k_{base} represent the dissolution rate coefficients of the three dissolution pathways mentioned above, a_{H^+} and a_{OH^-} are the activities of H^+ and OH^- ions, and n_{H^+} and n_{OH^-} are the partial orders of reactions promoted by H^+ and OH^- , respectively.

It is worth mentioning that the rate of dissolution of silicate and aluminosilicate minerals may change significantly with time due to the dynamic alteration of mineral surfaces during the incongruent dissolution or secondary precipitation processes (Yuan et al., 2019). Fig. 3A shows that during the incongruent dissolution of feldspar, Na^+ ions are preferentially leached and Si and Al are enriched on the surfaces. In this case, protons need to diffuse through the Na-depleted layer to contact with the fresh albite for dissolution, and the overall reaction will be slowed down by the diffusion process. Similarly, the precipitated secondary minerals coated on the surfaces may also increase the diffusion barrier and passivate the dissolution process (Fig. 3B).

Fig. 2 Rate of albite dissolution as a function of reaction pH at 25 °C. k ($\text{mol m}^{-2} \text{s}^{-1}$) represents the overall rate of mineral dissolution that is normalized by the surface area. Original data are from Chou L and Wollast R (1985) Steady-state kinetics and dissolution mechanisms of albite. *American Journal of Science* 285(10): 963.

(2019) A review of feldspar alteration and its geological significance in sedimentary basins: From shallow aquifers to deep hydrocarbon reservoirs. *Earth-Science Reviews*, 191: 114–140.

Iron (hydr)oxides are among the most investigated metal oxides due to their wide distribution. Because of the low solubility of Fe(III) minerals and changeable valence between Fe(III) and Fe(II), reductive dissolution is a key process to regulate the solubilization of most Fe(III) minerals in the environment. Reductive dissolution usually involves two different mechanisms, abiotic reaction of a reductant with the mineral's surfaces and microbially mediated mineral reduction. Organic matter, a redox active substance ubiquitous in the environment, can attach directly to the surfaces of minerals and may also act as electron shuttles to accelerate reduction of the mineral. Typical reductive dissolution processes consist of three steps, diffusion of the reductant molecules to the mineral surfaces, surface chemical reactions, and release of reaction products and their diffusion from the mineral surfaces. The surface chemical reactions, which are often the rate-limiting step, usually include precursor complex formation, electron transfer, and breakdown of the successor complex. The rate of reduction and extent of Fe minerals depend on the electron-donating ability of organic matter. Since the redox potentials of Fe(III)-Fe(II) are between those of reduced and oxidized nitrogen, carbon, sulfur, and oxygen redox species, reductive dissolution of Fe(III) minerals is vital for numerous environmental processes, including carbon storage, ocean productivity, greenhouse gas emissions, and the fate of toxic metal/metalloids.

Organic acids, including citric, ascorbic, oxalate, tartaric acid, and fumaric acid, have been shown to be capable of dissolving Fe minerals. Ascorbate, a commonly used antioxidant, is found widely in natural waters and can induce the reductive dissolution of Fe minerals. The interaction between ascorbate and Fe minerals can be described by following three basic steps (Huang et al., 2017). First, surface inner-sphere complexes of ascorbate (Asc) and Fe are formed on the Fe mineral surfaces,

Second, electron transfer occurs from ascorbate to the surface structural Fe(III), forming surface-bound Fe(II) species and ascorbate radicals ($\cdot\text{Asc}$),

Finally, the adsorbed Fe(II) is gradually released from Fe mineral surfaces into the aqueous phase,

The above organic acid-mediated reductive dissolution processes are influenced by various factors. The most important factor is the pH of the initial solution, and temperature also promotes the reductive dissolution of Fe minerals. Moreover, the chelating capacity of polycarboxylic acids can also affect the reductive dissolution of Fe minerals and more electrons can be transferred in the presence of organic substances with stronger chelating capacity.

Biotic dissolution of minerals

Microbially-mediated mineral dissolution also plays a significant role in regulating the geochemical cycling of elements and transformation/formation of various minerals such as clay minerals and Fe and Mn (hydr)oxides. The Fe(III) reducing bacteria couple the oxidation of inorganic or organic electron donors with the reduction of structural Fe(III) in secondary Fe minerals, which is a common process in an anoxic environment. The electron donors used by Fe(III)-reducing bacteria include carbohydrates, aromatic substances, dihydrogen, amino, and fatty acids. Generally, Fe(III) appears as either crystalline Fe oxides (e.g., hematite and goethite) or short-range-ordered Fe oxides (e.g., ferrihydrite). In almost all anaerobic environments, various bacteria such as *Shewanella* spp., *Geobacter* spp., *Albidiferax ferrireducens*, and hyperthermophilic *Archaea* have been shown to be capable of coupling the oxidation of inorganic or organic electron donors with the reduction of Fe minerals.

There are different pathways of electron transfer from bacteria to Fe(III) minerals as summarized in Fig. 4 (Melton et al., 2014). One of the most common ways of dissimilatory Fe reduction involves direct contact between the Fe(III) mineral surfaces and

Fig. 4 Pathways of electron transfer from bacteria to Fe(III) minerals. Reproduced with permission from Melton ED, Swanner ED, Behrens S, Schmidt C, Kappler A, (2014) The interplay of microbially mediated and abiotic reactions in the biogeochemical Fe cycle. *Nature Review Microbiology*, 12(12): 797–808.

proteins attached to outer cell wall. However, due to the poor solubility of Fe(III) minerals and the limited transition distance of an electron, several mechanisms have been put forward for the extracellular transfer of electrons from bacteria to Fe minerals. Bacteria may utilize chelating ligands (e.g., humic substances), which can form strong complexes with Fe and promote solubilization of Fe and rapid transfer of electrons. Redox-active Fe minerals (e.g., magnetite), reductive substances secreted by microbes (e.g., riboflavin), and redox-active electron shuttles (e.g., dissolved organic matter) can also be used as an intermediate for electron transfer between distant Fe minerals and intracellular electron transfer chain. In addition, bacteria may transfer electrons to Fe minerals through strategies that include redox-active pili (known as bacteria nanowires) and multistep electron hopping.

The physicochemical properties of Fe oxides, including crystallinity, shape, and particle size, could influence the Fe(III) bio-reduction. Iron minerals with a low degree of crystallinity usually are more likely to be reduced than highly crystalline ones. The exposed facets of Fe minerals during the reactions may also affect the reductive dissolution of the Fe mineral (Hu et al., 2020b). Fig. 5 shows that the rate of reduction of hematite {100} is less than that of hematite {001}, which can be explained by both the attachment of cells onto hematite surfaces and surface electrochemistry of hematite. Specifically, the resistance of hematite {001} is less than that of hematite {100}, therefore, hematite {100} is less favorable for accepting the extracellular electrons from bacteria. Moreover, hematite {001} has a high density of adsorption sites, resulting in more biomass adsorbed on its surfaces, which may reduce the distance of electron transport and thereby increase the rate of Fe(III) reduction.

In addition to the secondary minerals, soil microbes can also directly mediate or indirectly accelerate the dissolution of primary minerals, known as the microbial weathering process. One of the widely known microbially-mediated dissolution processes is the biotic oxidation of sulfide minerals in soil. The latter are present as either discrete sulfide phases (e.g., CuS (copper sulfide), Cu₂S (copper(I) sulfide), ZnS and PbS (lead sulfide)) or coprecipitates with major Fe-sulfide phases such as FeS₂ (e.g., chalcopyrite, CuFeS₂). When exposed with dissolved oxygen (O₂), the sulfide minerals can be oxidized through both abiotic or biotic pathways; the biotic pathways can significantly accelerate the mineral dissolution (Roden, 2008). For example, pyrite (FeS₂) the major sulfide mineral can be abiotically oxidized by the dissolved O₂, which releases the protons, ferrous ion, and sulfate ions,

The released ferrous Fe ions can be further oxidized biotically by *A. ferrooxidans* that are known as the Fe oxidizing acidophilic bacteria,

Although reaction (18) can also occur chemically, the rate is extremely slow at pH values below 4, whereas the rate of microbially catalyzed oxidation is several orders higher at pH < 4 (Fig. 6). In the sulfide oxidizing environment, solutions are often very acid due

to the release of protons from reactions (17) and (20), therefore, a considerable fraction of Fe^{3+} produced in reaction (18) is expected to be soluble (Fig. 6).

Subsequently, pyrite can be further oxidized by Fe^{3+} chemically,

The elemental sulfur from reaction (19) can also serve as the electron donor and chemical energy source for the sulfur-oxidizing bacteria or archaea, i.e., *A. thiooxidans* and *A. ferrooxidans*,

During the stepwise oxidizing process, the biotic and abiotic effects are coupled tightly, and jointly accelerate the overall dissolution rate of pyrite.

Precipitation of soil minerals

The precipitation process of soil minerals forms amorphous soil minerals with small particle size, poor crystallinity, and large specific surface area, and also causes the dissolved Fe, Al, Si (silicon), Ca (calcium), and Mn (the main mineralized elements in soil) to return to the solid phases from soil solutions. This dynamic process is an important part of the geochemical cycling of soil minerals, which has far-reaching implications for the behavior of soil pollutants and organic matter.

Newly precipitated Fe minerals are highly reactive and can interact with various elements/compounds due to their large specific surface areas, changeable surface charges, and surface activities. At the redox interfaces of the soil solution system, Fe^{2+} can be oxidized to Fe^{3+} , after which Fe^{3+} would further be precipitated to form amorphous Fe oxides such as ferrihydrite. Ferrihydrite has a small crystal size and is usually identified according to the number of its XRD peaks. In natural environments, all forms of ferrihydrite are widespread usually as young Fe oxides and play an important role as an active sorbent. Ferrihydrite is not stable and may transform to thermodynamically stable Fe oxides such as goethite and hematite, depending on the environmental conditions. Manganese (Mn) (oxyhydr)oxides with various mineral phases and oxidation states are also widespread in soils, and are usually formed through the oxidation of Mn(II) to higher valenced Mn. Birnessite ($\delta\text{-MnO}_2$) is the most common Mn oxide, and abiotic oxidation of Mn(II) by dissolved O_2 is an important pathway for birnessite formation, whereas biological oxidation of Mn(II) is regarded as the dominant pathway at certain pHs.

Clay minerals have abundant Al and Si, and usually have a layered structure. In addition to direct precipitation, metal sorption may induce the dissolution of cations held within the lattice structure of clay minerals, and the released cations can re-precipitate to multinuclear surface precipitates with the pre-adsorbing cations. For example, adsorbed Ni (nickel) on soil minerals can promote the dissolution of Si and Al in the crystal structure of soil minerals. The Al and Si released are then sequestered by the newly formed Ni surface precipitates, forming a mixed Ni-Al layered double hydroxide (LDH) precipitate (Fig. 7) (Shi et al., 2012). A significant Ni-LDH phase can occur within a few hours in soil environments and this process may last for days and months. During the aging process, Ni adsorbed on SOM may transfer slowly to the Ni-LDH phase. In general, LDHs are a class of clay minerals with brucite ($\text{Mg}(\text{OH})_2$)-like cationic layers containing anions in the hydrated interlayer for charge balance. The LDH phases are usually thermodynamically preferred to pure metal hydroxides, and might have significant implications for metal sequestration in soils.

Transformation of precipitated soil minerals

The newly precipitated soil minerals are usually meta-stable and have high Gibbs free energy to transform to soil minerals with greater crystallinity and smaller specific surface areas. Ferric Fe ions will precipitate with increasing pH, which forms ferrihydrite nanoparticles after the nucleation process, and ferrihydrite can transform further to well crystallized Fe oxides, for example, hematite and goethite. The formation of hematite begins with ferrihydrite aggregation, mainly through the dehydration of ferrihydrite. The hematite formation process also includes deprotonation of hydroxyl groups, creation of oxy-linkages, and redistribution of cation vacancies. While goethite formation is mainly through the dissolution and recrystallization of ferrihydrite, 2-line ferrihydrite can transform to hematite by a two-stage crystallization process, with goethite as an intermediate product. Hematite is a common iron oxide with the formula Fe₂O₃ and is widespread in rocks and soils. It has different morphologies at the nano scale, including ellipsoidal, cubic, plate-like, or rod nano particles, depending on the environmental conditions. Goethite (FeOOH) is one of the most widespread Fe oxides in natural environments and always has a needle-like morphology. Generally, hematite formation is favored under near-neutral conditions, and a higher temperature and ionic strength, whereas goethite formation is preferred under extreme pH conditions (e.g., less than 4, or greater than 12) and at a lower temperature and ionic strength.

Ferrihydrite can also transform to other iron oxides, for example, lepidocrocite and magnetite. During the microbially mediated Fe mineral reductive dissolution and transformation process (Shi et al., 2020), transmission electron microscopy (TEM) images have shown that ferrihydrite gradually transforms into biogenic magnetite (Fig. 8). The TEM images have also revealed that the newly formed magnetite nanoparticles have a size of 40–60 nm after 120-h transformation experiments. Moreover, with the presence of anions such as arsenic (As), the rates of Fe oxide transformation generally decrease. Fig. 8 shows that with the increase in As concentrations, the transformation of ferrihydrite to magnetite has slowed.

Sequestration of heavy metals and organic carbon in soil precipitates

Heavy metals and SOM can be adsorbed on or coprecipitated with minerals because of the abundant binding sites and large specific surface areas of freshly precipitated soil minerals. During the transformation process of precipitated minerals, adsorbed heavy metals have the potential to be incorporated into the crystal structure of minerals. Some elements, such as Co (cobalt), Cu, Ni, and Zn, might have a strong possibility of being incorporated into Fe oxides during the ferrihydrite transformation process. These elements usually have a similar atomic radius to Fe atoms. Some other elements, for example, Pb ions, cannot be incorporated easily into Fe oxide structures because of the larger atomic radius of Pb than that of Fe. However, under certain extreme environmental conditions (e.g., high pH and Pb concentrations), Pb ions might be able to enter the nano pores or defects within Fe oxides as revealed by the high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) imaging (Lu et al., 2020). Some Pb ions can even enlarge the lattice spacing of hematite and distribute along a specific zone axis of hematite during the ferrihydrite transformation process, indicating that some Pb ions might have amorphous substitution with Fe atoms (Fig. 9). Heavy metals within defects or with substitution into the crystal structure of minerals usually have low mobility, which has significant implications for the fate and transport of heavy metals in the environment.

During the formation and transformation processes of soil minerals, the interactions between SOM and minerals protect SOM from degradation and mineralization. At the global scale, mineral protection plays a key role in regulating the long-term stability of natural organic matter in the environment. Soil organic matter (SOM) is a complex mixture of organic macromolecules containing various reactive functional groups such as carboxylic, phenolic, amino, and thiol groups, which can either adsorb on or precipitate with soil minerals. Compared with the surface adsorption process, coprecipitation of SOM with minerals can usually sequester more organic matter. Fig. 10 shows that surface adsorption usually results in partial organic matter cover on dense ferrihydrite aggregates but little organic matter can penetrate into the aggregates (Kleber et al., 2015). For coprecipitates of organic matter with ferrihydrite, ferrihydrite nanoparticles are less aggregated and organic matter is more homogeneously distributed within ferrihydrite aggregates. Depending on the initial organic matter concentrations, some organic matter may be occluded within the pore spaces of ferrihydrite aggregates, providing a significant pathway for organic matter sequestration by ferrihydrite.

The SOM may slow down the Fe oxide transformation process and thus affect the interactions between organic matter and Fe oxides. The presence of organic matter may also affect the formation of the transformation products. During the Fe(II)-induced transformation of ferrihydrite coprecipitated with fulvic acids (FA) and arsenate ions (As), ferrihydrite (Fh) gradually transforms to a mixture of lepidocrocite (Lep) and goethite (Goe) as shown in Fig. 11 (Hu et al., 2020a). For ferrihydrite coprecipitates with FA and As, the line scans of STEM coupled with electron energy loss spectroscopy (EELS) show that the signals of C generally correlate well with both Fe and O, consistent with the conceptual model of organic matter distribution in ferrihydrite coprecipitates shown in Fig. 10. For the transformation products, there is a significant difference between lepidocrocite and goethite for organic C

distribution. For lepidocrocite, there is no accumulation of organic C on the edges of lepidocrocite nanoparticles, but organic matter molecules may be incorporated into its defects or pore spaces of lepidocrocite. In comparison, EELS line scans have clearly shown that organic C has accumulated on the edges of goethite nanoparticles, indicating that organic C is mainly adsorbed on the surfaces of goethite. Therefore, in addition to adsorption, the defects or nano pore spaces formed in the structures of Fe oxides may provide an effective way to sequester C through physical isolation, which has significant implications for predicting mineral transformation and C sequestration in the environment.

Summary

Dissolution and precipitation of minerals play critical roles in determining the physical properties and chemical composition of soil, and consequently control the speciation and reactivity of contaminants and determine the preservation capacity of SOM. In this chapter, we have provided an introduction to the knowledge of soil mineral dissolution and precipitation processes obtained during past decades. The saturation index (SI) that considers the mineral's specific solubility product (K_{sp}) and ion activity product in aqueous solution (IAP) can be referred to as the thermodynamic driving force of mineral dissolution and precipitation. As specific examples for the abiotic mineral dissolution process, proton promoted aluminosilicate dissolution and redox controlled iron oxide dissolution are described. The solution pH, organic ligands, and surface properties of minerals may jointly determine the rates of reaction and end products of mineral dissolution by various mechanisms. Moreover, the biotic mineral dissolution process is also described by pyrite oxidation and the reductive dissolution of Fe oxides. In the precipitation subsections, the nucleation, growth, and transformation processes of precipitated minerals are discussed. Moreover, the transformation of Fe oxides is discussed and the environmental significance of soil mineral dissolution and precipitation is addressed from the perspective of heavy metal and SOM sequestration. Because of the complex, heterogeneous, and highly dynamic nature of soil systems, further comprehensive studies that couple mineral dissolution/precipitation with other critical soil hydro-biogeochemical processes under broad spatial and temporal scales are expected to improve the mechanistic understanding and capability of model predictions of dynamic soil systems.

Abstract

Redox reactions are fundamental to life, and local heterogeneities in the soil create gradients in pH, redox and chemical concentrations that support chemical reactions. In situ monitoring of waters can distinguish abiotic and biotic reactions, and the analysis of temporal data makes it possible to establish the kinetics of these reactions. Field data show that the oxidation–reduction potential can vary over a wide range of pe in a few hours, and that fougérite can be a competitor of denitrification. Layered double hydroxides can drive self-organizing reactions, including redox reactions, usable for storage and replication of chemical information.

Key points

- redox reactions are fundamental to life.
- local heterogeneities in the soil create gradients in pH, redox and chemical concentrations that support chemical reactions.
- fougérite is a denitrification competitor.
- in situ monitoring of waters can distinguish abiotic and biotic reactions.
- the structure of the double layered hydroxides allows spontaneous redox reactions.
- auto-organization reactions are needed for information storage and replication.

Introduction

The soil, the fragile interface between the atmosphere, the hydrosphere and the lithosphere, is an environment and habitat for more than half, by mass, of the organisms living on Earth. Soils differ from mere weathered rock, because they show an approximately vertical differentiation, i.e., the soil horizon, that has been produced by the continual influence of percolating water and living organisms. Among the chemical reactions that act on the transformation of soils, oxidation–reduction reactions have a special place because by acting on the environment, they enable living organisms to recover the energy necessary for their metabolism. By studying both the solutions and the mineral and or organic constituents of the soil, redox reactions can be observed and measured in situ. The heterogeneity of the organization of soil constituents promotes the emergence of pH, redox and chemical

concentration gradients that control chemical reactions. Recent research shows that the mineralogical structure of double layered hydroxides can create steric environments that favor certain reactions, including oxidation–reduction reactions, information storage and replication.

Drivers of reactivity in soils

Heterogeneity, a need

Soils are porous media formed at the land surface by weathering processes mediated by biological, geological and hydrological phenomena. From the point of view of chemistry, the soil is a multi-component open environment, with biogeochemical systems containing solids, liquids and gases. That it is an open system means the soil exchanges both matter and energy with the surrounding atmosphere, biosphere and hydrosphere. These flows of matter and energy to, or from soils are highly variable in time and space, but they are the essential fluxes that cause the development of soils and govern the patterns of their functionalities, e.g., fertility... (Sposito, 2008).

Soil is a mixture of constituents in all three states, i.e., solid, liquid and gaseous (Fig. 1). We call “phase” a portion of matter bearing the same properties at any point in space (e.g., refraction index, density...). Geochemical and biochemical reactions redistribute matter and create local heterogeneities, sources of new possibilities for reaction. The gases in the soil mix very quickly, and despite the variability of the molecules that can constitute them, they form only one phase. Soil solutions do not mix as rapidly as gases.

Depending on the distribution and geometry of the solid constituents, pores of varying sizes, connected or not, define spaces where solutions of different chemical composition can co-exist. Finally, minerals with different crystal structures do not mix and each will be considered a separate phase.

For there to be a reaction between constituents in a soil, thermodynamic and or chemical, temperature, water state and or pressure imbalances must be present. There are two types of gradients: (i) gradients through an interface, either mineral or biological; (ii) gradients from one site to another, due to small diffusivity in the soil solution. Because of the small particle sizes, the number of atoms constituting the surface of the solid is proportionally larger than the number of atoms in the volume of the solid. For example, a solid in the form of a 20-nm diameter sphere exposes 5% of its atoms on its surface, while in the form of a 2-nm sphere, it exposes 60%. These imbalances are favored when physical and or chemical gradients are established between the constituents of the soil and the organisms that generate and maintain them throughout their life. This is observed, particularly in the rhizosphere where the mineral nutrition of plants takes place. In this process, there is a biological control, in addition to passive absorption. Plants take up nutrients mainly in the form of soluble cations, thus creating a charge deficit in the root environment. To maintain electrical neutrality, the plant emits protons toward the soil solution to compensate following a reaction such as:

where H is hydrogen and K is potassium.

Fig. 1 Heterogeneities and diversity of constituents in a soil observed at the micrometric scale.

Phase transitions

Biogeochemical reactions in soils lead to phase transitions of several types. Changes of state (i.e., solid/liquid, liquid/gas, etc.) are always characterized by sharp variations in volume, V , and therefore in enthalpy, H , entropy, S , and specific heat, C_p , at the transition point T_1 . Thus, we distinguish the first order cooperative transition phases, which can be illustrated by the gypsum–anhydrite transition in gypsum and saline soils under arid conditions. This transition is marked by the departure of two water molecules per cell and a change of crystal system. At the transition temperature (at constant pressure) the chemical potential, μ , of the constituent in the two states is the same, but the curve of μ as a function of T presents a discontinuity, which is explained by the fact that the two constituents do not have the same density (Fig. 2a). There are other transitions where no discontinuity of volume, enthalpy or entropy is observed (Fig. 2b). We then speak of second-order cooperative transitions, or transition λ . The transition by change of conformation of a protein by reorganization of its main chain is an example.

In many situations in soils, phase transitions, which are neither first order nor second order, can be observed and are called intermediate transitions or co-operative phenomena (Fig. 3) (Williams and Frausto da Silva, 1997).

The difference between first- and second-order changes is the degree of co-operation (see some examples in Table 1). For a first-order change it is sharp and global, applying to all atoms in the sample. For a second-order change it is local but extensive, statistically distributed and fluctuating. It is more likely that second-order changes will occur in weakly interacting systems with many energy states. We need to note that for many polymers, for example proteins and polynucleotides, second-order changes are usual; this is fundamental in biology and has important consequences in interactions between living organisms and the components of soils.

Fig. 2 Changes in thermodynamic properties accompanying first-order (a) and second-order (b) phase transitions at constant pressure. T is the temperature, T_1 the transition temperature, V is the volume, H the enthalpy, S the entropy and C_p the specific heat. In: Berthelin J, Munch JC, Coord Valentin C, Mariotti A Eds., Volume 1: Soils as a Key Component of the Critical Zone—Functions and Services, Geosciences Series, Soil Sets, ISTE, Wiley ed., pp. 81–115.

Fig. 3 (a) Variation of the chemical potential, μ , close to the temperature of a second-order transition process; (b) the distribution of energy over molecules or monomer units of a polymer in (1) a perfect crystal, (2) in solution, and (3) a weakly co-operative material such as some proteins; (c) the distribution of energy (E) within an energized polymer such as a protein that can oscillate their component parts along the x axis but not along the y or z directions. In each case the absolute value of E differs.

Table 1 Some examples of first- and second-order phase transitions.

	Transition	Comment
<i>First-order transition</i>		
S	Rhombic–monoclinic	Change in packing of S_8 molecules
$CaCO_3$	Aragonite–calcite	6- to 8- co-ordinate of Ca ions
<i>Second-order transition</i>		
MnO	Magnetic transformation	Spins aligned below Curie temperature
protein	Conformation change	Main chain reorganization
cell membrane + cholesterol	Fluidity change	Lipid packing altered

Oxido-reduction in soils

In soils, the geochemical systems where oxidation–reduction processes occur are non-equilibrium systems, and where thermodynamic equilibrium will often never be reached (Stumm and Stumm-Zollinger, 1971). For example, organic matter should not exist in the presence of most electron acceptors (e.g., SO_4^{2-} (sulfate), $FeOOH$ (ferric oxyhydroxide), NO_3^- (nitrate) . . .). However, organic matter exists in soils and can remain there for long periods (several thousand years). This is because to produce this organic matter, living organisms can decrease the significant kinetic barriers between redox couples and recover the energy of these relatively slow reactions (from milliseconds to minutes) to maintain the thermodynamic imbalances that allow them to live.

All manifestations of life are based on a series of chemical and physical processes, where all the transformations of matter are directly linked to changes in the energy situation of the cell. The system that allows the cell to have an energy reserve, available and for non-exclusive use, is oxidative phosphorylation (Fig. 4).

The phosphorylation of adenosine diphosphate (ADP) ($\Delta G = 3.35 \text{ kJ mol}^{-1}$) is coupled to a potential decrease in energy (about 300 mV) established between an electron donor (D) and an electron acceptor (A). The energy accumulator is adenosine triphosphate (ATP) and its hydrolysis releases 2.99 kJ mol^{-1} , 64% of which can be used freely by the organism. The ATP allows the cell to perform, independently and with a certain inertia all of the chemical, mechanical, osmotic and electrical work it needs. All the ingenuity of the living lies in the remarkable exploitation of this flow of electrons. Electrons do not circulate freely in the cell, they are exchanged by a series of discontinuous steps between an electron donor, which is in the reduced state, and an electron acceptor, which is in the oxidized state. The electrons thus culminate from one protein carrier to another to the final acceptor.

Non-equilibrium conditions suggest that the nature and extent of the redox reaction is controlled by several variables, such as the free energy gain produced by the reaction or the availability of suitable catalysts. In many cases, the catalytic activity is due to the enzymes of the microorganisms. But there are also several abiotic mediators of electron transport, such as organic compounds in a reduced state in an oxidizing medium or the surfaces of minerals containing reduced elements likely to oxidize, e.g., iron, manganese, sulfide.

**Fig. 4** Principle of the oxidative phosphorylation system.

When organic matter is no longer synthesized or repaired by the living organism and is not fossilized (e.g., coal, oil), it is transformed by oxidation into elementary mineral compounds; this oxidation is ambiguously called the “mineralization” of organic matter.

Redox-reactive minerals can serve as electron donors or acceptors both for abiotic reactants and or microbial metabolic processes.

Oxido-reduction: The chemical point of view

In chemistry, an oxidation–reduction reaction, or redox reaction, is a chemical reaction in which one or more electrons are transferred from one chemical species to another. Since the electron is not considered as an independent chemical species, demonstration of the transfer of electrons is obtained by splitting the oxidation–reduction reaction into two half-reactions: an oxidation reaction in which a chemical species acts as an electron donor and a reduction reaction in which another chemical species acts as an electron acceptor. Usually, the reduction reaction is written as:

the oxidation reaction is written as:

and the oxido-reduction reaction:

where A and B are the chemical species, whose index specifies the reduced or oxidized state of the component, $m, m', n, n', x, p, p', q$ and q' are the stoichiometric coefficients, e^- is the electron and H^+ is the proton in the solution.

A theory equivalent to that defining pH is proposed for “free electrons” of the solution. The Jorgensen’s oxidizability is defined by the negative value of the logarithm (base 10) of the activity of the electron in the solution, i.e., $pe = -\log[e^-]$. High positive values of pe preferentially point to the existence of oxidized compounds, i.e., electron acceptors while strongly negative values favor reduced compounds, i.e., free electron donors. Thus, by definition at equilibrium for the reaction:

the electron potential is:

$$pe = 1/x \{ -\log K_R + \log([B_{\text{ox}}]^{m'}/[B_{\text{red}}]^{p'}) - n' pH \} \quad (5)$$

with $[B_{\text{ox}}]$ the activity of compound B in oxidized state; $[B_{\text{red}}]$ the activity of compound B in reduced state; $pe = -\log[e^-]$ and $pH = -\log[H^+]$.

These equations enable us to predict the activity ratio of the proton acceptor and proton donor at any acidity state of an aqueous solution. In this way, pe - and pH -values are used to calculate the stability fields of redox species (e.g., Pourbaix’s diagrams) in a chemical system if it approaches equilibrium, independently of the time required and the reaction pathways necessary.

There are, however, several fundamental differences between the pH and pe values (Pfeifer, 2000). Acid–base equilibria always refer to the protolysis of the solvent, i.e., a proton acceptor reacts with water and de-protonates it, whereas a proton donor transfers protons to water to form H_3O^+ (hydronium ion). Hydrated protons are components of the solvent and quickly establish an equilibrium with dissolved acids or bases (this also holds true for the hydroxylated surfaces of many solid phases, Stumm, 1992). The pH is a well-defined variable for the intensity of proton transfer reactions, because a pH -electrode, i.e., the hydroxylated surface of a glass membrane, also establishes a rapid equilibrium with water. The pH can be measured and reproduced repeatedly in this way.

In contrast, redox equilibria refer to the standard hydrogen electrode. Consequently, pe describes the tendency to accept electrons from reactants, or donate them to the reactants and does not describe the extent of electron transfer from or to the solvent (Pfeifer, 2000). The life span of hydrated electrons is extremely small (of the order of 10^{-12} – 10^{-17} s). Thus, characterization of the redox state of an aqueous solution can be obtained only by the measurement of the activity ratios of certain redox couples, e.g., Fe^{2+}/Fe^{3+} , H_2/H_2O or H_2S/S^0 , that are not necessarily in equilibrium with the same value of pe .

In chemistry, the standard potential E^0 of the redox couples given in the tables is defined at $pH = 0$ and with the convention that the activity of the chemical species and the $[A_{\text{ox}}]/[A_{\text{red}}]$ ratio are equal to 1.

These conventions enable the classification of redox couples according to the value of the standard potential E^0 and thus prediction of the direction of the reaction (see for example, Fig. 5).

The direct application of this formalism, however, to a heterogeneous milieu such as soil is unsatisfactory because:

- the pH of a soil is never equal to 0;
- the activity of species in solution is rarely equal to 1;
- the activity of solids equal to 1 is an assumption that cannot be applied to minerals of variable chemical composition, or of small sizes; which excludes almost all minerals in the soil, that is 90 to 95% of its constituents.

Fig. 5 Order of the redox couples defined according to the standard potential E^0 at pH = 0, $[A_{\text{ox}}]/[A_{\text{red}}] = 1$. The arrow indicates the direction of the possible oxidation–reduction reaction between two couples.

Oxido-reduction: Application to natural environments

The various oxidation–reduction reactions possible in soils cannot be classified simply by order of increasing standard potential E^0 (value of the potential of the electron, pe , when $[A_{\text{ox}}]/[A_{\text{red}}] = 1$ and given in tables). On the one hand, the stoichiometric coefficients of the reduced and oxidized species and of H^+ vary from one reaction to another and, on the other hand, some reactions are homogeneous in solution, and others are heterogeneous, solid and solution. It is possible, however, to order the various reduction reactions by establishing, by convention, at a given pH by calculating the value of the electron potential, pe , for which the ratio of the activities of the reduced and oxidized species is greater than a threshold convention such that the reduced species is largely dominant. This leads to defining of “ pe_{critical} ” and “ Eh_{critical} ” ($Eh_{\text{critical}} = 0.05916 \text{ } pe_{\text{critical}}$, where 0.05916 is the Nernst factor at 25 °C).

For homogeneous reactions, the conventional $[A_{\text{red}}]/[A_{\text{ox}}]$ ratio is taken as 10^6 . For example, the reduction of nitrate to nitrite is practically complete when pe exceeds the critical value: $pe_{\text{critical}} = 4.35$ ($Eh_{\text{critical}} = 256 \text{ mV}$). This value is derived from the equilibrium equation:

$$\log ([\text{NO}_2^-]/[\text{NO}_3^-]) + 2\text{pH} + 2pe = \log K^0 \quad (6)$$

With $\log K^0 = 28.64$ at 298.15 K and 10^5 Pa , pH = 7 and $[\text{NO}_2^-]/[\text{NO}_3^-] = 10^6$.

For heterogeneous reactions, where the oxidized species is solid and dissolves during reduction, A_{red} is taken as 10^{-7} , assuming that the solid phase is pure and its activity A_{ox} is 1. For example, for the reaction of reductive dissolution of goethite, $\alpha\text{-FeOOH}$:

One obtains $pe_{\text{critical}} = 1.0$ ($Eh_{\text{critical}} = 59.2 \text{ mV}$), from the relationship:

$$\log ([\text{Fe}^{2+}]/[\text{FeOOH}_s]) + 3\text{pH} + pe = \log K^0, \quad (8)$$

where $\log K^0 \approx 15$ at 25 °C, 10^5 Pa , with pH = 7, $[\text{FeOOH}_s] = 1$ and $[\text{Fe}^{2+}] = 10^{-7}$.

By confusing, as a first approximation, the activity of Fe^{2+} with its concentration in the solution, this corresponds to an analytical measurement limit of $10^{-7} \text{ mol. L}^{-1}$ in the solution.

From thermodynamic data of the most stable species (Table 2), it is possible to establish a scale of sequential reduction potentials of N(V)/N(IV), Fe(III)/Fe(II), S(VI)/S(-II)... The classical order is obtained and steps larger than 100 mV separate the successive redox couples. However, the outcomes are quite different when labile or metastable species are considered, e.g., fougérite green rusts (GRs) for the iron system (Trolard and Bourrié, 1999). By placing the different iron pairs on the same pe_{critical} diagram as a function of pH, Fig. 6 shows that the values are distributed over a large area within the area of water stability. This suggests that: (i) the transfer of electrons in an iron-containing system at a given pH can occur over the entire domain of water stability (cf “Iron in soils” in this encyclopedia), because the $\text{Fe}^{\text{III}}/\text{Fe}^{2+}$ couple can respond to different levels of activation; (ii) metastable species can significantly alter redox potential values and thus mineral–solution equilibria and (iii) these species should not be overlooked, in particular, when seeking to identify the mineral which controls the activity of iron in solution.

Table 2 Thermodynamic data used to compute the pe_{critical} values.

Réactions	$\log K^0$	$pH = 6.0$	pe_{critical} $pH = 7.0$	$pH = 8.5$
$1/4 \text{ O}_2(\text{g}) + \text{H}^+ + \text{e}^- \rightleftharpoons 1/2 \text{ H}_2\text{O}(\text{l})$	20.78	14.6	13.6	12.1

^aValues in parentheses are not valid in the stability domain of water.

Modified from Trolard F, Bourrié G (1999) Influence des oxydes de fer de type « rouilles vertes » sur les séquences d'oxydo-réduction dans les sols. *Comptes-rendus de l'Académie des Sciences, Paris, Sciences de la terre et des planètes/Earth & Planetary Sciences* 329: 801-806.

Fig. 6 Variation in the critical potential, pe_{critical} in a system where fougurite green rusts may be present. Cl-GR = chloride fougurite, $\text{SO}_4\text{-GR}$ = sulfate fougurite; $\text{CO}_3\text{-GR}$ = carbonate green rust; OH-GR = fougurite, αFeOOH = goethite, γFeOOH = lepidocrocite. Modified from Trolard F, Bourrié G (1999) Influence des oxydes de fer de type « rouilles vertes » sur les séquences d'oxydo-réduction dans les sols. *Comptes-rendus de l'Académie des Sciences, Paris, Sciences de la terre et des planètes/Earth & Planetary Sciences* 329: 801–806.

The critical potential scales must therefore be constructed according to: (i) the labile, metastable and stable species that control the redox potential in solution, therefore the mineralogy, including nano-minerals and soil geochemistry; (ii) the pH of the environment and taking into account concentrations of the elements present in the soil solution, therefore according to the water geochemistry.

The rH measurements in the soils

The diagnostic criterion of reductic or gleyic properties is an rH value < 20 , with $rH \equiv -\log p\text{H}_2$ where $p\text{H}_2$ is the partial pressure of hydrogen, and rH is related to the redox potential, Eh, and pH by the relationship:

$$rH = Eh/0.029 + 2 \text{ pH}, \quad (9)$$

where Eh is expressed in mV and 0.029 is the approximate value of $\ln_{10}RT/2F$ at 298.15 K, $R (=8.3144598 \pm 0.0000048 \text{ J mol}^{-1} \text{ K}^{-1})$ is the ideal gas constant, $F (=96,485.33289 \pm 0.00059 \text{ C mol}^{-1})$ is the Faraday constant and T is the absolute temperature in kelvin.

It involves measuring both Eh and pH in the soil solution and the sample temperature; rH is related to pe and pH by:

$$rH = 2(pe + \text{pH}) \quad (10)$$

$$pe = \frac{F \text{ Eh}}{\ln_{10}RT}, \quad (11)$$

where Eh is the redox potential relative to the normal hydrogen electrode in volts.

The pH, Eh and temperature measurements recorded with a multiparametric probe in Fougères' forest in Brittany (France) and a rice (*Oryza sativa* L.) field in the Camargue, Provence (France) show large variations covering the whole domain of existence of aqueous Fe(II) and Fe(III) oxides (Fig. 7).

In this example, although the geological, pedo-climatic and soil formation contexts are very different between the forest of Fougères in Brittany and the rice fields in Camargue, Fig. 7 shows similarities between the recordings of Eh–pH dynamics between the two sites. In Brittany, the soils result from the alteration of granitic rocks in an oceanic climate and the study site is in a multisecular beech (*Fagus* L.) forest, while the soils of the Camargue result from carbonated fluvial sedimentary deposits in a Mediterranean climate, and the study site is in cultivated and irrigated rice fields. In both situations, hydromorphic soils are observed with more or less pronounced waterlogging depending on the season. The data on the free water of the soils were acquired in Fougères during winter and spring, and in the Camargue during the irrigation season, from April to October, at the rate of one measurement every hour for several months. The variation in pe–pH shows a definite pattern, with a fast decrease in pe, stabilization of pe between -3 and -4 , and oscillations of the system between two opposite states, linked to infiltration of oxygenated rainwater: an oxidizing and reducing environment with very few points between.

According to equation 10, the rH values in Fougères vary between 4 and 14.4, and in the Camargue between 4 and 8.5; these values are much lower than 20, which is the upper bound set for reducing media. The evolving patterns can almost be superimposed despite differences in the soil and climate, which suggests that the biogeochemical processes responsible for these dynamics are the same.

Evidence for biotic–abiotic reactions

The dynamics of rice growth in waterlogged rice field soils of the Camargue, which start with a few kilograms of seed per hectare to become 8–10 tons of dry matter per hectare at harvest in less than 6 months also involves strong biogeochemical dynamics, in particular pe–pH. Alternate flooding and drying conditions at the beginning of the crop season aim to get rid of the natural variety of rice that loses its grains (domesticated rice keeps its grain) and of some other weeds. Reducing conditions are maintained by flooding during all the cultivation period until just before the harvest. Two plots were instrumented and monitored during a complete rice growing season: in plot R178 the organic matter content in soil was very small (less than 3%) because the straw from the previous year's harvest was burned; in plot R179 the organic matter content was larger because the straw had been incorporated into the soil for several years during post-harvest tillage (Nawaz et al., 2013).

Fig. 7 Eh–pH dynamics registered in soil-free water using a multiparametric probe, in Fougères (a) and Camargue (b). From Bourrié G and Trolard F (2018) Chapter 1: Water quality in soils. In: Bourrié G (ed.), Soils as a Key Component of the Critical Zone, Vol. 4, Soils and Water Quality. Geosciences Series, Soils Set, Fig. 1.21, pp. 1–72. ISTE and Wiley Editions.

Fig. 8 shows that pe decreases very rapidly (points every hour are clearly distinct), then have low and quasi-constant values close to $pe = -4$. After the initial decrease in pe at quasi-constant pH, differences in pH occur at quasi-constant pe .

When compared with “critical” pe values, it seems that nitrate is largely unstable with respect to ammonium. When pe decreases, the system successively crosses the thermodynamic stability lines of lepidocrocite, goethite, hematite, and ultimately that of natural green rust, fougérite. The steady pe value is in the range of -3 to -4 . This is higher than the “critical” pe for methane formation and sulfate reduction, which are almost the same ~ -5 . This means that methane emission is possible, but should be limited by the abundance of sulfate due to the proximity of the sea.

A series of pH values were recorded during the first 45 days after flooding, just before pH returns to pH_{stat} as shown in Fig. 9.

The differences in pH are partly due to water management practices, the pH of irrigation water (Rhône river) is 0.5 of a unit higher than the pH of the soil solution, but they mostly result from urea applications applied 2 weeks before flooding. Urea is applied as the N fertilizer in both R178 and R179 plots, which results in a pH increase, according to the reaction:

Maximum pH occurs about 45 days after flooding. Then, pH relaxes to equilibrium, according to an exponential law. The different straw management techniques (burned straw versus straw incorporation) reflect in different characteristic times of relaxation: relaxation time with straw burning is almost twice as long (966 h) as that for straw incorporation (469 h). This correlated with the smaller dissolved organic carbon content and alkalinity of the soil solution, and to the diminution of surface acid–base sites in the organic matter of crop residues. Straw burning, therefore, decreases the buffering capacity of pH. The differences between measured and predicted pH by the relaxation exponential law show definite, regular oscillations (Fig. 10). The period of these oscillations is 24 h, as shown by the Fourier transforms (Nawaz et al., 2013).

Fig. 10 shows a sharp increase in pH after midnight and before sunrise, and a relatively slow decrease in pH in the afternoon. Temperature and pH are in opposite phase: pH is maximum when temperature is minimum and vice versa. During the night, in the absence of root absorption, the abiotic phenomenon of urea hydrolysis is dominant and results in an increase in pH; maximum pH is observed at night, with minimum temperatures. During the day, the biotic process of ammonium absorption by roots is dominant with the simultaneous release of H^+ that results in a decrease in pH due to the proton pump, and the classical rhizosphere effect (Nye, 1981); minimum pH is occurs during the day, with maximum temperatures.

Redox potential is poised by the dissolution or precipitation of iron oxides involving Fe(III) oxides (*sensu lato*), lepidocrocite, goethite, hematite and mixed Fe(II)—Fe(III) hydroxide, fougérite. This limits pe to the narrow range of -4 to -3 , which favors NH_4^+ (ammonium), although non negligible concentrations of nitrate are observed. Moreover, it prevents reduction from proceeding

Fig. 8 (pe , pH) variations in the Camargue with straw burned (R178) and straw incorporated (R179). Stability lines are drawn for $pFe = -7$ and the solubility products of the following iron oxides: G = goethite, H = hematite, L = lepidocrocite, F = fougérite (here computed with the formula $Fe_3(OH)_7$). Modified from Nawaz MF, Bourrié G, Trolard F, Mouret J-Cl, Henry P (2013) Effects of agronomic practices on the physico-chemical properties of soil waters in rice culture. *Turkish Journal of Agriculture and Forestry* 37: 195–202.

Fig. 9 Differences in average pH_{stat} and pH values over time in the soil solution of the different rice plots. For R178 (a), from 21/06/2009 to 09/08/2009 and for R179 (b); from 24/06/2009 to 14/07/2009. Points are measured data and the dotted curves are the fitted exponential equations: $\ln |pH - pH_{stat}| = -t/\tau$, where τ is the time of relaxation. Modified from Nawaz MF, Bourrié G, Trolard F, Mouret J-Cl, Henry P (2013) Effects of agronomic practices on the physico-chemical properties of soil waters in rice culture. *Turkish Journal of Agriculture and Forestry* 37: 195–202.

Fig. 10 Temperature and pH daily variations for R179.

toward extensive sulfate reduction and methanogenesis, though small amounts of sulfide were detected but probably limited by FeS (mackinawite) formation. With the large amount of sulfate from the Mediterranean-sea sulfate reduction is likely to prevent methanogenesis effectively in anaerobic pathways.

Redox reactions in soils are both biotic and abiotic. Transitions from the reduced to oxidized state may be controlled by differences in pe, but also by variation in pH at constant pe. These transitions are influenced by availability of oxygen from the air or as dissolved oxygen in rain. They are also affected by the variation in soil moisture, by waterlogging and fluctuations of the water table, by the input of organic matter, nitrogen fertilizers, such as urea, and by the proton pump. The variation in the controlling variables, pe and pH, in turn affect metabolic activities of aerobic and anaerobic microorganisms.

Layered double hydroxides: A solution for auto-organization of the reactions

If most of the oxido-reduction reactions in soils are controlled by living organisms, some minerals such as layered double hydroxides (LDHs) can, by their architecture, create abiotic environments favorable to redox reactions, store information and orientate the transfer of compounds.

Structure of layered double hydroxides (LDHs)

In soils, the clay fraction, defined by particles less than 2 μm in size, contains several families of minerals including phylites, in particular. When the structural layers are based on silica tetrahedra, they form clay minerals whose negative surface charge is compensated for by interlayer cations, which can be exchanged depending on the environmental conditions, i.e., cation exchange capacity. Other structural layers based on hydroxides form the layered double hydroxides (LDHs), whose positive surface charge is compensated by interlayered anions. These clays, improperly called “anionic clays,” whose structure allows anion exchange, also have an electrochemical capacity and magnetic properties.

The LDH compounds form a large group of minerals (Table 3) including green rusts, the natural form of which is fougérite.

The LDH structure is formed of stacked layers of edge-sharing metal octahedra containing divalent and trivalent metal ions separated by anions within the interlayer spaces. The range of composition of LDHs is very narrow and they differ mainly by the nature of the interlayer anion. The number of anions that may be intercalated per unit weight of LDH, known as the anion-exchange capacity depends on the charge density of the layer, i.e., the number of M^{3+} cations within the layer. The general structural formula can be expressed as:

$$[M^{II}_{1-x} M^{III}_x(\text{OH})_2] [x/nA^{-n}, m\text{H}_2\text{O}], \quad (13)$$

where, for example, M^{II} can be Mg (magnesium), Ni (nickel), Co (cobalt), Zn (zinc), Mn (manganese) and Fe (iron) and M^{III} can be Al (aluminum), Fe and Cr (chromium) (Sparks, 2003). All sites of the layers $[M^{II}_{1-x} M^{III}_x(\text{OH})_2]$ are occupied, therefore, the layer has a net positive charge x per formula unit, which is balanced by an equal negative charge from an interlayer anion A^{-n} , such as Cl^- (chloride), Br^- (bromide), I^- (iodide), NO_3^- (nitrate), OH^- (hydroxide), ClO_4^- (perchlorate) and CO_3^{2-} (carbonate). Water molecules are also present in the interlayer.

When considering order within the structure of LDH minerals there are three aspects to consider: (i) cations within a sheet along the (a, b) plane, (ii) anions within the interlayer along the (a, b) plane and, (iii) the order imparted when the LDH layers stack along the c [001] direction. The LDHs are the only known mineral structures that have both great plasticity in the (a, b) plane and fidelity along the c axis. For example, the structure of green rusts, which are particular LDHs, can react both in the structural brucite/amakinite layer, and in the interlayer space with more than 35 different chemical elements (Trolard et al., 2022).

The ordering of cations within a sheet along the (a, b) plane

In the hydroxide sheet, the octahedra of hydroxyl ligands are occupied by cations M with charges of +2 or +3. However, with Fe-LDH, to maintain the stability of the sheet, the close neighbors of an Fe^{3+} cation can be only divalent cations M^{2+} , otherwise spontaneous electrostatic repulsion of two neighboring Fe^{3+} cations leads to an oxolation reaction with the loss of an H^+ (Bourrié et al., 2004). This imposes an M^{2+}/Fe^{3+} stoichiometric ratio of 2 (Fig. 11a). However, for the structure of LDH to be stable, a minimum of Fe^{3+} must be present in the structure of the hydroxide sheet. Experimentally, it has been shown that a quarter of the sites must be occupied by a trivalent cation and the distance between two trivalent cations should be at least, $a\sqrt{3}$.

The ordering of anions within the interlayer along the (a, b) plane

Anions in LDH interlayers are often considered dynamic, precluding the possibility of long-range order, but the geometry of the anion leads to different modes of their organization in the interlayer. For a given LDH, interlayered anions compensate for the excess positive charge of the layer. However, steric hindrance limits the number of anions the interlayer can accommodate, which depends on the charge and size of the anion. For monovalent spherical anions such as OH^- , Cl^- , F^- (fluoride), Br^- , ... the first-nearest neighbor sites of the anion site cannot be occupied by another anion. The minimal distance between two spherical

Table 3 Structural formula of some natural layered double hydroxides.

Mineral	Structural formula	Interlayer anion
Fougérite	$[\text{Mg}_y \text{Fe}^{II}_{1-x} \text{Fe}^{III}_x (\text{OH})_2] [x/n A^{-n}, m\text{H}_2\text{O}]$	Possible: OH^- , Cl^- , CO_3^{2-} ...
Meixnerite	$[\text{Mg}_6 \text{Al}_2 (\text{OH})_{16}] [(\text{OH})_2, 4 \text{H}_2\text{O}]$	OH^-
Woodallite	$[\text{Mg}_6 \text{Cr}_2 (\text{OH})_{16}] [(\text{Cl}^-)_2, 4 \text{H}_2\text{O}]$	Cl^-
Iowaite	$[\text{Mg}_4 \text{Fe}^{III} (\text{OH})_{10}] [(\text{Cl}^-), 2 \text{H}_2\text{O}]$	Cl^-
Takovite	$[\text{Ni}_6 \text{Al}_2 (\text{OH})_{16}] [(\text{CO}_3^{2-}, \text{OH}^-), 4 \text{H}_2\text{O}]$	OH^- , CO_3^{2-}
Hydrotalcite	$[\text{Mg}_6 \text{Al}_2 (\text{OH})_{16}] [(\text{CO}_3^{2-}), 4 \text{H}_2\text{O}]$	CO_3^{2-}
Pyroaurite	$[\text{Mg}_6 \text{Fe}^{III} (\text{OH})_{16}] [(\text{CO}_3^{2-}), 4 \text{H}_2\text{O}]$	CO_3^{2-}

Fig. 11 (a) Possible positions of Fe^{3+} in the hydroxide sheet; (b) Stacking sequence at the scale of M cation hydroxide layers, anion interlayers and OH^- layers, along the threefold axis of Fe-LDH (Cl^-), Fe-LDH (CO_3^{2-}) and Fe-LDH(SO_4^{2-}) structures. A, B, C or a, b, c positions represent the sites in the hexagonal pavement, i.e., geometric assemblage of OH^- ions. Panel A: Modified from Bourrié G, Trolard F, Refait Ph, Feder F (2004) A solid solution model for Fe(II) - Fe(III) - Mg(II) green rusts and fougurite and estimation of their Gibbs free energies of formation. *Clays and Clay Minerals* 52: 383–395. Panel B: Modified from Génin JMR, Ruby C (2004) Anion and cation distributions in Fe(II)-Fe(III) hydroxysalt green rusts from Mössbauer analysis (carbonate, chloride, sulphate, ...); the “fougurite” mineral. *Solid State Sciences* 6: 705–718. Doi: 10.1016/j.solidstatesciences.2004.03.021.

anions is $a\sqrt{3}$ and the maximum number of anions, on the basis of 2 OH per mole formula, would reach 1/3 (Génin and Ruby, 2004). There is only one layer of water molecules in the interlayer and the structure is rhombohedral, with space group R-3m. For divalent anions with a three-dimensional geometry such as sulfate, oxalate, selenate. . . , there will be two layers of water molecules and the structure is a trigonal type with a P-3m1 space group (Fig. 11b). The screening effect of the two water layers allows more freedom for the lateral position of anions. Large organic anions like benzene sulfonate, terephthalate or larger monovalent aliphatic carboxylate anions, Cx, . . . may undergo rotations and site-hopping motions at high frequencies, as evidenced by using combined Nuclear Magnetic Resonance (NMR), Infrared (IR) Spectroscopy and digital modeling (Greenwell and Coveney, 2006). Thus, a long-range order of anions in the interlayer is not needed in the (*a*, *b*) plane, but the correlated distribution of both cations and anions is propagated through the crystal structure along the threefold *c*-axis.

Ordering along the *c*-axis

The existence of super-periodicity (propagation of cation ordering along the *c*-axis is a result of not only cation ordering, but also of cation–anion ordering; the existence of cation ordering is only likely at M^{II}/M^{III} ratios of 2 as only one arrangement can exist where the positive M^{III} centers are not adjacent (Drits and Bookin, 2006). Without being exhaustive, the existence of a long-range order along the crystallographic *c*-axis is important for information storage within LDH crystals and subsequent transfer of information at their surface.

Spontaneous abiotic reduction of nitrate by fougérite green rusts

Experimentally, while in solution NO_3^- cannot be reduced by Fe^{2+} , but chloride (Cl-GR1) or sulfated (SO_4^- GR2) green rusts reduce nitrates stoichiometrically into ammonium in several hours under abiotic conditions (Hansen et al., 2001). The rates of reduction increase with increasing nitrate concentrations up to some threshold concentrations, depending on the initial conditions of the reaction, above which no further increase in reduction rates takes place. The kinetics of the reaction depends on the type of interlayer anion, the layer charge and relative content of Fe^{II} in the hydroxide layers. In addition, pH modifies the rate of reduction by a direct effect of H^+ in the redox reaction following first-order kinetics and the proton affects nitrate adsorption onto reactive sites of iron grains (Huang and Zhang, 2004).

Thermodynamic calculations show that the reduction of nitrate proceeds largely before the reduction of ferric oxides, following the classical sequence when fougérite green rusts are absent (Trolard and Bourrié, 1999). In the field when fougérite is present, and irrespective of the nature of the compensating anion, the redox sequence is determined by the pH of the milieu (Fig. 12). This suggests that nitrate and fougérite can compete as electron acceptors for microflora in anaerobic conditions. At pH 6, redox buffering by fougérite protects nitrate and thus bypasses denitrification. At pH 8.5, denitrification is possible in presence of fougérite. However, in this case, nitrate can be spontaneously reduced by fougérite to NH_4^+ .

The layered structure of the mineral explains the particular reactivity of fougérite in abiotic conditions. For example, Fig. 13 summarizes the steps of reduction of nitrate by SO_4 -GR2: the first step is an anion exchange between nitrate and sulfate in the interlayer of the GR, and SO_4 -GR2 transforms into unstable NO_3 -GR1.

Under these conditions, a minimum of 8 divalent Fe^{2+} are immediate neighbors of NO_3^- . The reduction of NO_3^- to NH_4^+ can thus proceed spontaneously with simultaneous transfer of 8 electrons from Fe^{2+} to N. In the layer, the $\text{Fe}^{II}\text{—OH—Fe}^{II}$ bonds transform into $\text{Fe}^{III}\text{—O—Fe}^{III}$ by oxolation, releasing $8e^-$ and 8H^+ ; four additional H^+ equilibrate the two sulfate anions released; $8e^-$ and 10H^+ are necessary for each NH_4^+ , so that there is a net release of 2 protons. The GR oxidizes into hematite.

Fig. 12 Field dynamics of Fe(II) and NO_3^- in soil solution. At the end of summer, no Fe(II) is present in solution. At the beginning of autumn, nitrate concentration decreases to zero before Fe(II) is released in solution. This is the classical scheme (a). Then, in winter, fluctuations of Fe(II) are observed due to partial entry of oxygen from rainwater. Fougérite precipitates and competes with nitrate inducing the coexistence of N(V) and Fe(II) in solution, which is well explained by the occurrence of the redox couple fougérite/ Fe^{2+} in the system (b). From Trolard F, Bourrié G (2008) Geochemistry of green rusts and fougérite: A reevaluation of Fe cycle in soils. *Advances in Agronomy* 99: chapter 5, 227–287.

Fig. 13 Reaction scheme for the abiotic reduction of nitrate by $\text{SO}_4\text{-GR2}$: (a) initial state of the interlayer in $\text{SO}_4\text{-GR2}$; (b) exchange of sulfate by nitrate and collapse of the interlayer; (c) initiation of reduction of nitrate by eight neighboring Fe^{2+} ions, and final state of ammonium production before ammonium release to solution. Modified from Trolard F, Bourrié G (2008) Geochemistry of green rusts and fougérite: A reevaluation of Fe cycle in soils. *Advances in Agronomy* 99: chapter 5, 227–287.

The half-reactions and the net reaction can be written as follows:

The LDHs as supports of the auto-organization of reactions

The relationship between information theory and the evolution of life has become a research area in its own right (Avery, 2003) that requires exploration of abiotic mineral–organic combinations favorable to the self-organization of reactions, which are essential for the storage, replication and transfer of information. The layered double hydroxide compounds, in addition to concentrating and reacting with or catalyzing reactions of important prebiotic molecules, provide a superior coding environment relative to the cationic clays and could have served as prebiotic “ribozymes,” which would eventually be the first RNA materials to be produced and, ultimately, genetic takeover by nucleic acid systems occurred (Greenwell and Coveney, 2006).

The replication of an LDH is constrained by the distribution of interlayer anions, which reproduces the charge distribution of the octahedral layers. If in the plane (a , b) the distribution is variable within certain limits (see above), in the direction perpendicular to the sheets along the c -axis the copy is constrained. Thus, periodic boundary conditions are imposed in all three space directions (Fig. 14). The ideal dianions would have some directional nature with respect to the two negative charges, and the charge would neutralize one positive site on the LDH sheet above, and one on the LDH sheet below. If we consider starting with one LDH sheet and placing the ideal dianions at positive sites, the dianion has one negative charge to satisfy (Fig. 14a). When a second LDH sheet is considered (Fig. 14b), the LDH sheet charge sites not neutralized from the dianions in the previous layer are filled to give a string of numbers opposite to the previous one. A different arrangement of anions would have a different information content.

This conceptual model can be extended further by considering the nature of the binary information that is displayed at the surface of LDH crystals (Fig. 15). If the same mineral has polytypes with a two-layer repeat or three-layer repeat (Fig. 15b), this has important implications for the information encoded at the external surfaces of the LDH minerals. In a two-layer repeat system (Fig. 15a), the arrangement of sites on either side of the crystal will be complementary, rather than mirror images.

Fig. 14 Schematic representation of information storage in LDH interlayers for different arrangements of dianion: (a) with 2 hydroxide layers and (b) with 3 hydroxide layers. Filled LDH sheet sites can be denoted “1,” and non-charge balanced sites as “0.” Modified from Greenwell HC, Coveney PV (2006) Layered double hydroxide minerals as possible prebiotic information storage and transfer compounds. *Origins of Life and Evolution of Biospheres* 36: 13–37.

This complementarity can be considered a rudimentary form of “base pairing.” In a three-layer repeat cell (Fig. 15b), the arrangement of sites at the top face of the crystal will be the same as that of sites at the bottom face, so far as the information content is concerned. In the suggested mechanism (Fig. 15c) for information transfer between LDH crystals, the surface adsorbed anions are electrostatic sites on the LDH surface H-bond with other anions, setting up an inverse bonding surface (c1), or a complementary surface (c2). We can note that in these idealized systems where electrostatic interactions dominate, the local sites of occupancy in the lattice are not differentiated from those of the interlayer species (modified from Greenwell and Coveney, 2006). In three dimensions the opposing external surfaces of a three-layer polytype LDH are enantiomers, i.e., non-superimposable mirror images. Under such conditions, the adsorption of prochiral anionic monomers and their subsequent oligomerization might conceivably result in the formation of molecules that are enantiomers—molecules that are non-superimposable mirror images of each other (Greenwell and Coveney, 2006).

An area of interest in the study of LDHs is the biomimetic nature of LDH catalysts. Computer simulation shows that the enhanced reactivity of some organo-LDH catalysts may be due to the variable layer separation and amphiphilic nature of hosted bilayers. It results in increased selectivity and controlled organization of substrate reactant molecules that effectively provide an inorganic or organic-hybrid pseudo-enzyme active site.

In the particular case of LDH green rusts, such as fougérite, Branscomb and Russel (2019) suggest that pyrophosphate formation, as a form of energy storage, can occur. The mechanism would involve a progression of pyrophosphate accompanied by magnesium following an undulation of the sheet, of about 1 nm, facilitated by the conduction of electrons in the hydroxide sheet. In fougérite, unlike other LDHs, the bivalent and trivalent ions are of the same nature, and an electron can pass from an Fe^{2+} ion to the Fe^{3+} ion, i.e., by the propagation of polaron holes of about 1.2 nm.

Fig. 15 Schematic information encoded at the external surfaces of LDH polytypes: (a) with a two-layer repeat structure and (b) three-layer repeat structure and (c) a suggested mechanism for information transfer between LDH crystals. Fig. 15—Cont'd

Conclusion

Local heterogeneities in the soil create gradients in pH, redox and chemical composition that support chemical reactions. Redox measurement requires the identification of electroactive redox couples at the platinum electrode and speciation of chemical species in the soil solution... Redox reactions couple different biogeochemical cycles through both biotic (aerobic or anaerobic) and abiotic processes. Specifically, the nitrogen cycle involves competition between biotic reduction (denitrification) and direct abiotic reduction from nitrate to ammonium. In this process, fougérite plays a major role. In addition, LDHs and especially fougérite can accommodate different anions, which results in variation of the interlayer length. The reactants can move in a restricted space, compared to the 3-D space of the free solution. Thus LDHs, by their 2-D structure can support auto-organization of reactions that facilitate chemical reactions, including redox reactions. They are also good mineral candidates for the storage and replication of information over long-range order both in the plane (a , b) and along the c -axis, perpendicular to the sheets.

Abstract

Sorption of organic chemicals to soil particles governs their mobility, reactivity, and bioavailability in soil. This chapter deals with physisorption of both nonionic and ionic species. The various types of sorption that may occur are discussed, together with the intermolecular forces involved in the context of the nature of different particles that occur in soil, including oxide minerals, clays, hard and soft organic matter, and pyrogenic organic materials. The chapter also focuses on sorption equilibrium processes and touches on sorption kinetics.

Key points

- Sorption is a key underlying process in soils regulating transport, bioavailability and reactivity of organic compounds.
- Sorption includes all steps from extraction of the molecular entity from the aqueous phase, rearrangement of the solid phase to accept the entity, and establishment of intermolecular forces between the entity and the solid surface or matrix.
- Depending on the sorbent and sorbing molecule, sorption can occur as solid-phase dissolution (partitioning), binding to discrete surface sites, condensation in pores, or dissolution in or on water films associated with particles.
- Important driving forces for sorption of nonionic compounds are the hydrophobic effect and combinations of the weak intermolecular forces, dispersion, induction, electrostatic, and hydrogen bonding, depending on solute molecular structure.
- In addition to the above, organic ions can sorb by anion or cation exchange, ion-pair sorption, formation of charge-assisted hydrogen bonds with weak acid groups, or ligation with metal ions underlying mineral surfaces.
- Free energy relationships between sorption and solute structure and sorbent parameters have been proposed but are still unsatisfactory for polar and ionic compounds and lack translatability among soils.
- Sorption and desorption can exhibit slow stages due to the presence of highly viscous organic matter absorptive phases, tortuous pore networks within individual particles or particle aggregates, and steric effects as intra-particle pore dimensions approach molecular dimensions.
- Sorption to organic matter is primarily by partitioning but the softness or hardness of the organic matter can strongly affect the magnitude and linearity of sorption.
- Sorption to pyrogenic carbonaceous matter occurs by adsorption and pore-filling.

Introduction

Organic chemicals enter soils through the intentional use of chemicals, such as pesticides or fire-fighting products; the application of biosolids to farmlands; and the disposal or accidental release of petrochemicals, industrial wastes, and consumer wastes. Some compounds have negative effects on the environment and public health. A key process in soils that regulates the transport, bioavailability and reactivity of organic compounds is sorption. 'Sorption' and the reverse, 'desorption,' refer to the process of molecular exchange between the gas or solution phase and an immobile phase (the sorbent). The potentially sorbing molecule is called the solute (sometimes the sorptive) and the sorbed component is referred to as the 'sorbate.'

Sorption may be categorized by the type of intermolecular attractive forces between sorbate and sorbent. Ordinary physical sorption ('physisorption') involves relatively weak intermolecular forces, while chemisorption involves strong bonding of a covalent nature. Physisorption is, by far, the most common type encountered in the context of soil and environmental sciences, and will be the exclusive focus here. Chemisorption occurs for only a few types of environmental contaminants—e.g., amines reacting with ketone, aldehyde or quinone functional groups in SOM (soil organic matter) giving the imine or Michael addition product—and is irreversible or quasi-reversible (Li et al., 2000). Chemisorption may also result following prior thermochemical, photochemical, or enzymatic conversion (Dec and Bollag, 2000) of a compound to a reactive intermediate that then couples covalently with SOM. Such coupling reactions are technically outside the definition of sorption, since the molecules undergoing coupling are transformed species, not the original ones. Physisorption is a necessary first step to chemisorption and any other transformations that occur on or within soil particles.

The reactive mineral components in soils are silicate clays and oxyhydroxide minerals of Si (silicon), Fe (iron), Al (aluminium), Mg (magnesium), Mn (manganese), etc. Soil organic matter comprises the totality of substances derived from biomass, mainly of plant and microbial origin, in various stages of decomposition and diagenesis. A fraction (typically small) of SOM may be fire-derived matter. Soil organic matter is the predominant sorbent of most neutral organic compounds except at very low SOM content or very low moisture content. Ionic species can interact strongly with both SOM and mineral components.

General considerations

Categories

Physisorption processes are often broadly classified as 'absorption' or 'adsorption.' Absorption (also called 'solid-phase dissolution' and 'partitioning') occurs when molecules penetrate the solid–fluid interface and are able to intermingle with the internal molecular or atomic matrix of the sorbent. Soil organic matter is the only natural component of soils that is penetrable in this way, but polluted soils may contain additional penetrable absorptive phases such as solvents, oils, tars, plastics, etc.

Adsorption is a term used in the phenomenological sense to imply association at a solid–fluid interface. Mechanistically, however, adsorption may encompass several qualitatively different processes, including binding of molecules independently to discrete interfacial sites, partitioning of molecules into an ordered hydration phase near the surface, condensation of the molecules into a liquid-like or solid-like state in small pores, and adsorption of molecules on the surfaces of water films associated with the particles. These processes will be discussed in more detail as this chapter progresses.

Thermodynamics

Sorption from water may be written as a series of steps (Eqs. 1a–1d) summing to the overall net reaction in Eq. (1e):

Step 1a represents the removal of solute x from the water to the gas phase, where $\{ \}$ symbolizes the solvation (hydration) shell around x , and $\cdots$ represents the cavity left behind by the vacated solute molecule. Step 1b represents collapse of the cavity and reconfiguration of solvation-shell water molecules to the bulk water state represented by $()$. Step 1c is reorganization of the sorbent matrix ($\blacksquare$) to some altered state ($\blacksquare'$) that may be necessary to accommodate the sorbate, such as displacement of water or other

sorbed molecules into solution and structural changes such as swelling and pore flexing. Little is known about matrix changes and their effects on sorption equilibrium. Finally, step 1d represents the formation of bonds between sorbate and the altered sorbent.

When sorption occurs from the vapor state steps 1a and 1b do not apply and net sorption is the sum of steps 1c and 1d:

$$x_g + \blacksquare = x-\blacksquare' \quad (1f)$$

The curve defining the equilibrium relationship at a given temperature between the sorbed-phase concentration S and fluid-phase concentration C is the 'sorption isotherm.' Various models have been used to describe the isotherm depending on the mechanism(s) postulated.

It is convenient to define the 'sorption distribution ratio,' K_d , as:

$$K_d = \frac{S}{C}, \quad (2)$$

where C is expressed in units of pressure or moles per unit volume. The units of S depend on convention and whether sorption occurs by adsorption or absorption. For adsorption they may be based on surface area or pore volume, and for absorption on solid volume. However, these properties are often not known accurately and so dry weight is commonly used as a surrogate. The K_d is concentration dependent unless the isotherm is linear.

The K_d is related to the Gibb's free energy of sorption, ΔG_{sorp}^0 by

$$\ln K_d + \text{const} = -\frac{\Delta G_{\text{sorp}}^0}{RT}, \quad (3)$$

where R is the ideal gas constant and T is temperature. A constant 'const' is needed to convert the practical units of K_d to thermodynamic units, since K_d must be dimensionless and expressed as a mole fraction relative to a reference state. While the reference state for the liquid phase is well defined, that for the solid phase is not; thus, the value of 'const' is generally unknown. The ΔG_{sorp}^0 , which is concentration dependent when K_d is concentration dependent, encompasses all enthalpy and entropy changes that occur during sorption. That is, the position of equilibrium depends on i) the difference in enthalpy between all sorbate-sorbent and all solute-water interactions, and ii) the difference in entropy associated with each of the steps 1a-1d. There are virtually no examples where the contributions of these factors have been fully delineated.

Forces involved

The fundamental forces between solute and surface are represented by Eq. (1d) Physisorption involves the so-called 'weak' intermolecular forces: coulombic, dispersion, induction, electrostatic, and hydrogen (H) bonding (Israelachvili, 1992). These forces act simultaneously in combinations permitted by the structures of the interacting species. Coulombic force is the attractive or repulsive force between ions of opposite or like charge, and it is proportional to the distance separating the ions. Dispersion is the mutual attraction of momentary dipoles produced by the synchronization of electronic motion in interacting species. Induction is the attraction of a permanent dipole or charge in one species with the dipole it induces in the other. Electrostatic (distinguished from coulombic) includes dipole-dipole and charge-dipole forces, as well as analogous multiple forces. The strengths of dispersion, induction, and electrostatic (often lumped as 'London-van der Waals forces') depend on the molecular area of contact, separation distance (to the inverse sixth power), orientation, and applicable molecular properties: charge, dipole moment, ionization potential and polarizability.

The H-bond can be written $(\text{DH} \cdots \text{A})$, where D and :A are proton donor and proton acceptor groups. Hydrogen bonds can vary tremendously in strength. Most ordinary H-bonds contain O (oxygen), N (nitrogen), or S (sulfur) as terminal atoms, range in strength from 2 to 10 kcal mol⁻¹, and are essentially of dipole-dipole character. Much weaker H-bonds are known, such as between a donor and the π system of an aromatic ring or the halogen atom of an electrophilic carbon-halogen bond. Hydrogen bonding between a contaminant and sites on soil particles must compete with H-bonding between water molecules and the same sites. In a water-rich environment it is questionable whether compounds forming ordinary H-bonds, and especially weaker H-bonds, can out-compete water molecules for H-bonding sites.

In general, the strength of an H bond is inversely related to the difference in the acid dissociation constants of DH and AH⁺, ΔpK_a . As the ΔpK_a approaches zero, the bond strengthens, the proton is more equally shared, and the bond takes on covalent character (Gilli and Gilli, 2009). A family of very strong H-bonds exists, but the category most relevant to aqueous systems in the environmentally relevant pH range (~3 to ~9) is the 'charge-assisted H-bond' (CAHB), which forms between weak acids or bases and where one or both terminal atoms bear a charge. The CAHB category includes the (-)CAHB where both donor and acceptor atoms are negative: $(-\text{O}^- \cdots \text{H}^+ \cdots \text{O}^-)$ or $(-\text{N}^- \cdots \text{H}^+ \cdots \text{O}^-)$, and the (+/-)CAHB, when one is negative and the other neutral: $(-\text{O}^- \cdots \text{H}^+ \cdots \text{N}-)$. The CAHB reaches strengths of as much as 35 kcal mol⁻¹. The H-bond between a carboxylic acid and its conjugate anion, $\text{RCO}_2^- \cdots \text{H}^+ \cdots \text{O}_2\text{CR}$, for which ΔpK_a is zero, is among the strongest of H-bonds known among organic compounds. The bond is akin to the CAHB in hydrogen difluoride, $\text{F}^- \cdots \text{H}^+ \cdots \text{F}$, the strongest of all H-bonds known. There are many examples of weak acid and weak base compounds of environmental concern with pK_a values in the environmental pH range, including carboxylic acids, phenols, amines, heterocyclic amines, sulfonamides, and others. Soil organic matter is rich in weak acid functional groups with intrinsic pK_a values close to those of weak organic acids or base contaminants and therefore can form a CAHB with them. The CAHB equilibrium is rapid and reversible. Several examples of CAHB formation in soil-relevant systems have been documented.

Another important driving force for sorption from aqueous solution is the hydrophobic effect, which is a solution-centered effect. The hydrophobic effect is due to entropy and enthalpy costs associated with the more ordered alignment of water molecules near the apolar regions of the dissolved solute, as well as the consequent disruption of water–water hydrogen bonds there. (Apolar molecules or regions of molecules are those not strongly polarized and lacking appreciable H-bonding capability). For a series of compounds of related structure (e.g., aromatic hydrocarbons), K_d is found to correlate with the molar refractive index, the *n*-octanol–water partition coefficient (K_{ow}), or the sub-cooled water solubility, often used as surrogates for a compound's net hydrophobic character. This is true whether the sorbent domain is the polar surface of a mineral, or the comparatively apolar surface or interior of organic matter.

Sorption of nonionic compounds

Sorption of nonionic compounds to mineral solids

Minerals present two kinds of environments for sorption: (i) the hydroxylated surface found on hydrous oxide minerals and the edges of aluminosilicate clays, and (ii) the interlayers of layer silicate clays, which contain siloxane surfaces of varying charge density.

Hydroxylated surfaces have –OH groups protruding into solution from the topmost layer of lattice metal ions. Sorption of apolar compounds from dilute solution to low-porosity hydrous oxide surfaces is proportional to mineral surface area and is not very sensitive to surface charge, solution pH, or solution ionic strength (although high ionic strength may reduce water solubility and increase the tendency for sorption). Sorption of apolar compounds is also proportional to the hydrophobicity indices mentioned above. While data are sparse, sorption tends to be endothermic and sorption isotherms tend to be linear to slightly nonlinear. Sorption to minerals has been covered well by [Schwarzenbach et al. \(2017\)](#).

There is good reason to believe that sorption of apolar compounds to hydroxylated surfaces occurs by partitioning (i.e., absorption) of the sorbate into the 'vicinal water layer'—the semi-ordered multilayer of water under the influence of the surface. This is depicted as 'B' in [Fig. 1A](#). However, apolar compounds are thought unable to penetrate the closest 1–2 layers of water molecules, and therefore do not contact the surface. This is inferred from the observation that sorption of apolar organic vapors is strongly suppressed by water vapor, and that, per unit surface area, the heat of adsorption of organic molecules is much smaller than that of water. Compounds capable of H-bonding to surface hydroxyl groups may be able to penetrate the vicinal water layer and compete with strongly bound water molecules for surface sites ('A' in [Fig. 1A](#)).

The siloxane surface exists on the faces of many layer silicate clays and consists of O atoms bridging underlying Si^{IV} atoms ([Fig. 1B](#)). The O atoms may have a permanent negative charge, depending on whether they lie near a point of isomorphic metal ion substitution in the underlying lattice. The charged sites are closely associated with metal cations, and the surface in the vicinity of the charge is strongly hydrophilic. Polar sorbates may hydrogen bond to metal ion-coordinated water molecules. If it has an appropriate functional group, a sorbate may coordinate directly with a metal ion. The neutral regions between surface charges are hydrophobic or only weakly hydrophilic; hence, apolar molecules or parts of molecules may compete favorably with water for the bare surface in those regions. Sorption in clay interlayers is affected by interlayer accessibility to the solute. The charge density and the exchangeable cation with its hydration sphere control the interlayer spacing and the size of the adsorption surface available for incoming molecules.

The sorbate may also condense on surfaces or in small pores, depending on the abundance of water and the partial pressure or concentration of the compound. The condensate is regarded as a liquid-like or disordered-crystalline state depending on its freezing point. Due to capillary forces condensation in pores progresses from the smallest to the largest of pores (or narrowest to widest part of an individual pore) as the partial pressure or concentration increases ([Fig. 1C](#)).

Water has a strong negative effect on vapor adsorption to soils. Sorption of organic vapors decreases by an order of magnitude or more as the soil moisture content increases to approximately the wilting point, which corresponds to an average of 3–5 molecular layers of water ([Poulsen et al., 2000](#)) ([Fig. 2](#)). This inhibition is due to competition by water molecules for pore volume space and polar surface sites on inorganic surfaces. At moisture contents above the wilting point sorption approaches what it would be in water-saturated soil.

When dealing with sorption of vapors to unsaturated soils it is often necessary to include the amount of dissolved in liquid water coating surfaces and in pores, apart from the vicinal water. That water is technically considered part of the 'immobile phase.' Sorption may occur by a combination of aqueous-phase dissolution ('C' in [Fig. 1A](#)) and vapor-phase adsorption at the gas-water interface (D in [Fig. 1A](#)) ([Costanza and Brusseau, 2000](#)). The latter is especially important for compounds like alkanes that are highly insoluble in water. Finally, sorption of organic chemicals to minerals can be strongly affected by the presence of initially dissolved organic matter on their surfaces.

Sorption of nonionic compounds to soil organic matter

General considerations

Soil organic matter is usually the preferred sorbent of neutral compounds in soils because it offers a relatively hydrophobic domain for hydrophobic molecules. Whether sorption to SOM dominates total sorption in the soil depends on its content and the relative sorbate affinity for it. A 'rule of thumb' is that sorption to SOM becomes dominant when the soil organic carbon (OC) concentration exceeds 0.1% dry weight.

Fig. 1 Depiction of different types of sorption in mineral particles. Box I. Interaction with discrete sites on the hydroxylated surface (A); partitioning in the vicinal water layer on the hydroxylated surface (B); dissolution in water films (C); and adsorption on the surface of water films (D). Box II. Sorption in a clay interlayer: left to right, direct coordination to interlayer metal ion; association with the uncharged siloxane surface; and hydrogen bonding to a metal-coordinated water molecule. Box III. Condensation in a small pore.

Sorption isotherms in SOM and SOM-rich soils are often fitted by a power law known as the Freundlich equation,

$$S = K_F C^N \quad (4)$$

where K_F is an affinity-capacity coefficient and N is an exponent reflecting deviation from linearity of the relationship. The value of N is typically ≤ 1 , reflecting a constant ($N = 1$) to diminishing ($N < 1$) affinity of a solute for the solid with increasing loading, and may vary depending on the range of concentrations over which it is measured. The Freundlich model can be derived from the classical thermodynamic Langmuir model, which postulates competition between solute and water molecules for sites on a surface

Fig. 2 Toluene sorption coefficient (K_D') and soil–water potential (ψ) as functions of volumetric water content in Lundgaard soil (1.1% organic carbon). The 'Henry's law' line is the calculated sorption assuming dissolution into water and aqueous–solid partitioning only (i.e., zero vapor–solid sorption). From Poulsen TG, Yamaguchi T, Moldrup P, de Jonge LW, and Rolston DE (2000) Predicting volatile organic vapor sorption from soil specific surface area and texture. *Journal of Environmental Quality* 29: 1642–1649.

of a specific energy, by assuming a population of sites of different energy exists that varies from zero to infinity. It should be noted that all sorption tends toward linearity below a certain concentration (the so-called 'Henry's law' region), a result that the Freundlich equation fails to predict.

When $N = 1$, the isotherm is given simply by

$$S = K_p C, \quad (5)$$

where K_p is equal to K_d and is referred to as the 'partition coefficient.' Many researchers have taken N to be 1 to simplify sorption terms in solute transport and bioavailability models.

On the assumption that sorption occurs exclusively to the SOM fraction, the distribution, Freundlich, or partition coefficient is often normalized to the fraction of OC (f_{oc}) in the soil; i.e.,

$$K_{oc} = K_d (\text{or } K_F \text{ or } K_p) f_{oc}^{-1} \quad (6)$$

Note that K_{oc} cannot be regarded as a universal constant since SOM is not uniform from place to place—in fact, K_{oc} may vary by an order of magnitude depending on its composition.

Linear free energy relationships between K_{oc} and parameters that represent hydrophobic properties, such as the octanol–water partition coefficient K_{ow} , water solubility, parachor (quantity related to surface tension), connectivity index, or UNIFAC functional-group activity coefficients, have been tested extensively. Such relationships work best for a set of closely-related compounds in a given soil, the reason being that the enthalpy and entropy of Eqs. (1a)–(1d) depend on sorbate molecular structure. Polyparameter linear free-energy relationships have also attracted interest (Endo and Goss, 2014). Such models use various molecular descriptors and system parameters to describe sorption, and fit experimental isotherms better than the single-parameter models for a given sorbent. However, none was designed to take into account nonlinearity, and system parameters found in complex, highly heterogeneous solids like soil and carbonaceous sorbents are difficult to define.

Solution pH and ionic strength have only modest (and inconsistent) effects on sorption of neutral compounds to SOM.

Nature of soil organic matter as a sorbent

Soil organic matter is a complex mixture of fresh to highly refractory components. The refractory components (often called 'humic substances') may also contain recognizable fragments of carbohydrates and proteins covalently attached to, or sequestered in, the solid phase. Humic substances are operationally defined as consisting of fulvic acid (soluble at all pH), humic acid (soluble in alkaline solution), and humin (insoluble at all pH and typically strongly associated with inorganic particles). The SOM fraction may also contain ancient materials such as kerogens and coaly particles. Kerogens are biogenic, macromolecular substances that have undergone low-temperature chemical and physical diagenesis over geologic time. 'Kerogens' are abundant in soft coals and shale and may be found in soils due to re-working processes. Hard coals (coaly type particles) are biogenic macromolecular substances that have been subjected to higher temperature and pressure (catagenesis) over geologic time and are found in some soils. Pyrogenic carbonaceous matter (PCM; sometimes called 'black carbon') is the carbonaceous byproduct of biomass burning (char) or fossil-fuel combustion (soot). The PCM in soil may comprise a trace to a small fraction of total organic C, but can be at larger concentrations in disturbed areas. The soil water also contains 'dissolved' organic matter (DOM). This ranges from small, truly-dissolved molecules to colloidal particles. The DOM entities are regarded as supramolecular aggregates of smaller molecules. Organic compounds can partition into these entities, although somewhat less effectively than into solid SOM.

Sorption to humic substances and kerogen

Humic substances and kerogens are considered to be random-network macromolecular solids; that is, they are composed of large molecules (a few hundred to many thousands of Daltons) of heterogeneous primary structure that aggregate randomly to form a three-dimensional phase. This phase is variously hydrated depending on the humidity. Charged groups such as carboxylate may coordinate with free metal ions to the top layer lattice metals of minerals. From fulvic acid to humic acid to humin to kerogen, there is a trend of increasing average molecular weight, apolar character, C content, mean fused aromatic ring size, density, crosslinking, and 'hardness.'

For humics and kerogens, absorption rather than adsorption is a better description of what occurs (Chiou, 2002). Surface areas are too small to support an adsorption interpretation. Organic molecules may penetrate the surface due to the solid's flexible nature and intermingle with the strands of macromolecules in the interior. A similar, 'solid-phase dissolution' paradigm for small molecules sorbed by synthetic organic polymers is well established. Sorption to humic substances appears to be slightly exothermic, although few data exist.

However, sorption to humics and kerogens is more complex than just simple partitioning (Huang et al., 1997; Pignatello, 2011; Xia and Pignatello, 2001). According to established polymer theory, amorphous macromolecular solids may exist in 'rubbery' (soft) or 'glassy' (hard) states, depending on temperature. These states differ in physical properties and sorbent behavior. The rubbery state is more expanded and the macromolecular segments have greater mobility. Sorption in rubbery solids is similar to dissolution in a viscous liquid in that specific sorption sites are fleeting and sorbed molecules experience an average chemical environment. This results in a linear isotherm like Eq. (5) and noncompetitive sorption behavior when multiple solutes are present. The glassy state is more dense and rigid. Because it is incompletely relaxed, the glassy state contains internal voids that are not filled by macromolecules and are poorly interconnected. These voids (or 'holes') are of molecular dimensions and may accommodate one or a few sorbate molecules. Hence, sorption in the glassy state exhibits dual-mode sorption behavior. One mode is 'dissolution' in the bulk solid which is linear and noncompetitive. The other mode is 'hole-filling' in the voids that is best modeled by a Langmuir-type equation. The dual-mode isotherm is given by (Xing and Pignatello, 1997):

$$S = K_D C + \frac{S_H^{\max} K_H C}{1 + K_H C}, \quad (7)$$

where K_D is the dissolution domain partition coefficient, and $S_H^{\max}$ and K_H are the hole domain capacity and affinity parameter, respectively. Eq. (7) predicts nonlinear and competitive sorption in multi-solute systems, both of which have been observed for many soils, humic acids extracted from soil then reconstituted in particulate form, and kerogens.

In the context of SOM, holes may be regarded as semi-permanent voids within the folds of individual macromolecules, between macromolecules, or between macromolecules and the mineral surface to which they are anchored, as illustrated in Fig. 3A. When Eq. (7) is applied to natural materials, (a) the K_D term represents the sum of partition coefficients for all rubbery domains present and the dissolution domains of all glassy substances present; and (b) the Langmuir term represents a weighted average of holes of different sorption potential. The affinity for a given solute is somewhat greater in holes than in the dissolution domain because in the latter a cavity has to be created to accommodate the sorbing molecule, which costs free energy.

As loading of the compound increases the isotherm may become more complex. The glassy state may become softened ('plasticized') by the sorbate, causing it to convert to the rubbery state and the holes to disappear. At high loadings the isotherm may begin to curve upwards relative to the solution concentration axis due to swelling (Xia and Pignatello, 2001). The glass-to-rubber transition temperature of some natural substances has been measured, including wet and dry humic acids (43–72 °C), coals (>300 °C), and wet lignin (60–90 °C) (Huang et al., 1997). Lignin is an amorphous, random macromolecular polymer from the woody parts of plants that is regarded as a major precursor of terrestrial humic substances. Whole soil SOM may exhibit multiple glass transitions due to its heterogeneous nature. Synthetic polymers, humic acids, and coals all have been shown to have a large internal surface area associated with the holes.

Fig. 4 shows sorption of the hydrophobic compound phenanthrene in SOM. Phenanthrene sorption is nonlinear ($N = 0.772$) and the dual-mode model fits well. Langmuir hole-filling type of sorption dominates overall sorption until the aqueous concentration reaches $0.14 \mu\text{g mL}^{-1}$, where partitioning then predominates. The overall dissolution coefficient is $4330 \mu\text{L g}^{-1}$ and Langmuir (hole) sorption capacity is $961 \mu\text{g g}^{-1}$. If the surface of this SOM sample (specific surface area, $0.88 \text{ m}^2 \text{ g}^{-1}$) were as rigid as a mineral, the maximal (external) surface coverage would be only $286 \mu\text{g g}^{-1}$ calculated from the molecular volume of phenanthrene as $182 \text{ cm}^3 \text{ mole}^{-1}$. Clearly, phenanthrene molecules have diffused into and sorbed within the SOM matrix, as opposed to being adsorbed on the surface.

Nonlinearity and competitive effects tend to increase in the expected order of increasing glassy character of the solid: dissolved humic acid < particulate humic acid < whole soil SOM < humin < kerogen. Artificially cross-linking the humic acid by flocculating it with polyvalent metal ions (e.g., Al^{3+}) decreases isotherm linearity and enhances competition by a second compound.

In general, diagenetic alteration of SOM increases aromaticity and promotes higher sorption, greater nonlinearity, and more intense competitive behavior than geologically younger samples. Many investigations report positive correlations between a sorption coefficient and the percent aromatic C of SOM, deviation from linearity, and intensity of competition. Recent research indicates that aliphatic components of SOM, particularly the paraffinic groups, can also significantly sorb apolar compounds and give rise to nonlinearity (Chefetz et al., 2000). Both amorphous and crystalline paraffinic regions have been identified by solid state NMR (nuclear magnetic resonance) spectroscopy (Xing and Chen, 1999). It has been suggested that the sorbate partitions into the flexible, amorphous paraffinic regions, but not in the crystalline regions. To account for the nonlinearity of paraffinic regions, it is

Fig. 3 Sorption in soil organic matter fractions. (A) Macromolecular solids such as humic substances and kerogens: sorbate may undergo solid-phase dissolution in domains composed of macromolecules in a relatively fluid state and hole-filling in voids within the organic phase and between the organic phase and the mineral surface. (B) Micrographitic substances such as PCM: sorbate may adsorb in shallow micropores and some may penetrate into deep micropores between polyaromatic platelets.

Fig. 4 Phenanthrene sorption by a soil with a large organic content. Solid line is the dual-mode fit assuming only one type of Langmuir (hole) site and solid circles are actual data points; dotted and dashed lines are contributions from partitioning and Langmuir (hole) type sorption, respectively. The maximum surface sorption capacity calculated from the surface area and molecular size is $286 \mu\text{g g}^{-1}$. The Freundlich model parameters (Eq. 4) are $K_F = 5610 (\mu\text{g g}^{-1}) (\mu\text{g mL}^{-1})^{-N}$ and $N = 0.772$ (curve not shown).

Fig. 5 Schematic configuration showing the distribution of crystalline ($\square$ -) and amorphous ($\circ$ -) aliphatic organic carbons (A). Interaction of the aliphatic carbons with a clay mineral surface ($\blacksquare$) rearranges part of the amorphous domain into a condensed configuration ($\triangle$ -) having nm-sized holes (B). These holes are the locus of adsorption sites responsible for nonlinear and competitive sorption. From Gunasekara AS and Xing B (2003) Sorption and desorption of naphthalene by soil organic matter: Importance of aromatic and aliphatic components. *Journal of Environmental Quality* 32: 240–246.

proposed that amorphous layers located at mineral interfaces become less flexible (harder), providing holes that act as adsorption sites (Gunasekara and Xing, 2003) (Fig. 5). This proposal is consistent with reports that nonlinearity and competitive sorption observed for humic acids adsorbed on minerals are greater compared with non-sorbed humic acids.

Sorption of nonionic compounds to pyrogenic carbonaceous matter (PCM)

With increasing temperature and heating time, the anoxic pyrolysis of lignocellulosic biomass evolves through several distinct physical–chemical states of increasing polyaromatic character, culminating in a turbostratic state of disordered graphitic microcrystallites. The polyaromatic sheets may be functionalized along the edges with hydroxyl, carboxyl, keto or other groups. Aliphatic C is converted to aromatic C at $\sim 450^\circ\text{C}$. The structure is very rigid and highly porous. The specific surface area depends on the heating conditions and can reach $600\text{ m}^2\text{ g}^{-1}$ or higher. Most of the surface area lies in mesopores (2–50 nm) and micropores ($<2\text{ nm}$ effective diameter), which are considered to be slit-shaped. Sorption occurs mainly by adsorption and pore-filling mechanisms (Figs. 1–III and 3). Pore filling at large concentrations can cause measurable swelling because small pores are expandable due to the local pressure of the sorbate.

Sorption isotherms of neutral compounds on PCM tend not to fit well to either the Freundlich or Langmuir models. For example, the isotherm of benzene in a wood charcoal is a reverse S shape, with a linear region from 10^{-7} to 10^{-4} times its water solubility (Braidia et al., 2003). Sorption of neutral compounds from water to graphite or activated carbon is exothermic. Sorption to PCM depends on surface area and pore-size distribution. Compared to non-pyrogenic forms of SOM, PCM has a greater affinity for organic compounds due primarily to their higher surface area and porosity. Another important property contributing to greater sorbent affinity is their aromatic character. The aromatic interface can be more closely approached than the alkane surface for steric reasons, permitting greater dispersion with sorbing molecules. (This is one reason why solvent–water partition coefficients of nonionic compounds are greater for aromatic solvents like benzene than aliphatic solvents like n-octanol and n-heptane.) It has been found that adsorption energy to wood chars correlates with fused ring size up to a certain size (~ 55 carbons) because polarizability increases with ring size up to that point (Yang et al., 2021). Chemical and biological oxidation processes such as those that occur during weathering of PCM in soil introduce O functionality into PCM surfaces that attract water molecules. This is disadvantageous to sorption because the bound water molecules compete for available surface sites. Lastly, it must be emphasized

that sorption of chemicals to PCM is strongly affected by the presence of dissolved organic matter. Such substances can bind to the surfaces of PCM where they can influence sorption by competing for sorption sites and blocking access to pore networks.

Proposed models for soils or sediments that contain both the ordinary softer matter (humics plus kerogen) and PCM take the form:

$$S = (1 - r_{\text{PC}}) \cdot K_{\text{p}} C + r_{\text{PC}} \cdot f_{\text{PC}}(C), \quad (8)$$

where r_{PC} is the ratio of pyrogenic carbon (PC) relative to the total organic carbon, and $f_{\text{PC}}(C)$ is a nonlinear function of dissolved concentration C describing sorption to PC. Predicting sorption with such models is problematic. Since PCM is a broad continuum of materials it is unclear how best to quantify r_{PC} (chemothermal or wet oxidation method?), which $f_{\text{PC}}(C)$ should be used, and what reference material is appropriate. As already mentioned, K_{p} is not strictly concentration-independent for a given soil and is not a universal constant. Dual sorbent models are able to predict pore water concentrations of highly hydrophobic compounds only to within about 2 orders of magnitude (Arp et al., 2009).

Kinetics of sorption

The rates of uptake and release of chemicals from soil particles play a role in controlling their mobility and bioavailability in soil (Pignatello, 2000; Pignatello, 2011; Alexander, 1995). In well-mixed soil–water systems it been shown experimentally that sorbate uptake is biphasic, with most occurring within a few hours, whereas days, weeks, or even months may be required to reach full equilibrium, depending on the compound and soil. Desorption that is induced by dilution of the liquid phase or reducing the pressure is almost always considerably slower than uptake for reasons that are unclear. Moreover, exhaustive desorption to water or air may reveal a minor fraction that seems permanently bound, yet is recoverable by solvent extraction or other vigorous means. Fractions that become highly resistant to desorption have been generated in purely inorganic as well as purely organic reference materials.

In general, soil particles have structural features that can hinder molecular diffusion of molecules to and from available sites. These features include highly viscous absorptive phases, tortuous pore networks within individual particles and the interstices of particle aggregates, and narrow pores. Models based on pore diffusion and intra-organic matter diffusion as the rate-limiting have been presented in the literature. Diffusion rates in soils are frequently independent of nominal particle radius, implying that the controlling diffusion length scale is much smaller—perhaps as small as 10–100 nm. In general, intraparticle sorption or desorption rate coefficients decrease with increasing molecular size due to steric hindrance of diffusion.

Diffusion depends strongly on the nature and geometry of the diffusing medium, the boundary conditions, and the local concentration (more correctly, chemical potential) gradient across boundaries. Classical mathematical diffusion laws are difficult to apply to soils due to their heterogeneous nature both compositionally and geometrically. Evidence suggests that diffusivity follows the order: humic acid > humin > kerogen or coal. Diffusion coefficients of toluene, *n*-hexane, and acetone in pressed humic acid disks are in the range 10^{-8} – 10^{-9} cm² s⁻¹, about the same as in rubbery polymers and are 3–4 orders of magnitude smaller than those in water. Diffusion within PCM has received little attention. From studies on homogeneous reference materials (Rouquerol et al., 1999) it is known that diffusion in fixed-pore networks is retarded by sorption to pore walls and tortuosity (deviation from straight-line paths and degree of pore connectivity). Diffusion in micropores, where pore openings are not much larger than the diffusant diameter, is also slowed by steric effects.

To avoid difficulties inherent in the application of diffusion models to soils, many people have employed non-mechanistic rate laws based on simpler mathematics. Recently published ones include the two-compartment, multi-compartment, and stochastic models. Although meeting with some success, they lack translatability to new systems. The two-compartment model, popular in soil column and bioavailability experiments, partitions the sorbate into instantaneous and kinetic compartments. The kinetic compartment has first-order terms for the forward and reverse steps. The multi-compartment model is popular in batch desorption experiments in which molecules are instantly removed as they desorb either by a stream of gas or by including a large excess of a polymeric sorbent in the suspension. The multi-compartment model assumes that desorption occurs concurrently from ‘fast,’ ‘slow,’ and sometimes ‘very slow’ compartments, each described by a first-order term. Stochastic models assume that the rate can be described with an array of equilibrium sorption coefficients and or first-order rate constants that are distributed continuously according to a probability density function. Slow kinetics play an important role in sorption isotherm hysteresis, in which the desorption branch does not coincide with the sorption branch. Hysteresis can be due to insufficient time allowed for equilibrium or irreversible alterations of the sorbent structure caused by uptake of the solute (Pignatello, 2011). Further discussion of sorption kinetics in the context of hysteresis will be covered in another chapter.

Sorption of organic ions

Ionic and ionizable organic compounds (IOC) constitute an important category of compounds of environmental concern found in soil and sediments. It includes many pesticides, pharmaceuticals, personal care compounds, surfactants, endocrine disrupting compounds, and per- and poly-fluoroalkyl (PFAS) substances. Examples of permanently charged functional groups or groups that are always charged under normal pH conditions in soil–water systems (pH ~3 to ~9) include R_4N^+ , sulfur heterocyclic ions, RSO_3^- , R_fCO_2^- , where R is any organic group and R_f is a perfluoroalkyl group. Examples of functional groups with pH-dependent charge

include primary, secondary and tertiary amines, heterocyclic amines, carboxylic acids, arylsulfonamides, and phenols. The sorption of ionizable compounds can vary tremendously with pH as the measured pH transitions through the pK_a value.

In the case of weak acids the neutral form of the molecule usually sorbs more intensely than the anionic form due to its greater hydrophobicity. In the case of weak bases, the contrast is not so clear because, although the cationic form is less hydrophobic than the neutral form, it can associate strongly with anionic sites on soil particles.

Organic ions undergo the same weak physisorption forces with soil particles as do nonionic molecules, plus other driving forces owing to their charge. One is ion exchange sorption, in which the organic ion replaces the 'natural' anion (e.g., $X^- = Cl^-$) or cation (e.g., $M^+ = Na^+$) initially associated with the solid (■) (Eqs. 9a and 9b).

A second driving force is ion-pair sorption, in which the organic ion pairs up with a counterion from solution before associating with the solid (Eqs. 10a and 10b).

Charge neutrality must be preserved in the transfers of reactions 9 and 10. Similar equations, properly balanced, can be written for polyvalent organic ions and counterions (e.g., Mg^{2+}). Eqs (9a) and (9b) are driven to the right by physisorptive interactions of the part of the organic ion not bearing the charge, and to the left by large concentrations of counterions. Cation exchange is more important than anion exchange in most cases due to the prevalence of negative charges on soil particles at near-neutral pH.

Ion pairs can partition into OM phases and in small pores of PCM and minerals. In contrast to ion exchange, large counterion concentrations control the equilibrium of reaction 10 to the right. Sorption is often found to exceed the measured cation or anion exchange capacity of the soil, which are based on sorption of inorganic ions (usually, NH_4^+ (ammonium) or Br^- (bromide)); ion-pair sorption is a likely explanation. Zwitterions, which contain sites of opposing charge within the same molecule, have not been studied thoroughly.

Carboxylate and some other weak acid anions sorb to PCM more strongly than expected considering that pH at the point of zero charge of these materials is typically above pH 4—i.e., their surfaces have an excess of negative charge. One explanation is the formation of a charge-assisted hydrogen bond (–)CAHB, as discussed above. The reaction between a weak acid anion D^- and a weak acid group on the sorbent, such as the carboxylate group, can be written:

This reaction has been conclusively demonstrated for reactions between simple weak acids and PCM, such as biochar and carbon nanotubes (e.g., Teixeira et al., 2011; Li et al., 2013). Reaction (11) is most favorable at a pH near the mean pK_a of DH and PCM anionic group. Upon sorption of D^- species such as carboxylate, sulfonaminate ($R-SO_2NH^-$), and other organic anions, the pH of the solution has been observed to increase, which is consistent with hydroxide ion generation in reaction 13. Moreover, competitive displacement of bound D^- has been shown to be much more effective when the competitor contains a (–)CAHB-capable functional group, compared to one that does not. Potential (–)CAHB reactions with non-pyrogenic SOM are likely but have not yet been demonstrated conclusively.

A third driving force for ion sorption, which is open only to organic anions, is ligand exchange with metals. Ligand–metal bonds may form between carboxylate, phenolate, thiolate, sulfonate, or phosphate groups on the sorbate, and metal ions—especially Fe^{3+} and Al^{3+} —on the surface of minerals or within SOM, usually in exchange for hydroxide (or water) ligands, e.g.:

where $\equiv$ represents the surface, M is a metal ion, and L^- is the sorbing ligand. Reaction (12) is more favorable when L^- is bidentate—for example, salicylate, oxalate, catecholate or *o*-phthalate and their derivatives. In that case the ligand can coordinate through both functional groups to a single metal ion or to adjacent metal ions. It is also possible for L^- to coordinate to a metal ion attached to SOM through an appropriate functional group on the humic structure. In that case, L is considered linked to SOM through a cation bridge. The energetics and kinetics of surface ligand exchange reactions are not well characterized. The intrinsic equilibrium constant seems to depend on structure in the same way as the corresponding reaction in solution between the ligand and free metal ion.

A fourth category of ion sorption occurs at the unhindered interface between water and oxide minerals (Korotky, 2000). The surface can be described as the flat plane of a mixture of positive $\equiv S-OH_2^+$ or negative $\equiv S-O^-$ sites depending on pH and ionic strength. The surface creates an electric double layer, where the charge at the surface is balanced by a 'diffuse layer' of counterions in solution near the charged mineral surface. Depending on the model used, the electric potential decreases linearly or exponentially with distance from the surface. These models have been applied predominantly to inorganic electrolytes and have been poorly tested with organic ions.

Concluding remarks

Sorption is a critical underlying process governing all types of behavior of chemicals in soil. With rare exceptions organic molecules or ions in soil spend the vast majority of their time in the sorbed state compared to the gaseous or dissolved states. Mobility from one soil parcel to the next is possible only if sorptive bonds are broken in the first stage and made in the second. Soil dwelling organisms—apparently, even single-cell organisms—lack access to molecules in the sorbed state. Thus, contaminant mobility and bioavailability of chemicals in soil depend not only on the position of the sorption equilibrium but also on the rates of sorption and desorption. Sorption is a highly complex process because it involves a variety of different types of chemicals, multiple fundamental forces acting in combination, multiple sorbent materials whose contributions are not necessarily additive, and constantly changing conditions in the soil aqueous phase. Soils are not uniform around the world. Although tens of thousands of studies have been devoted to sorption in soils, no model has yet been put forward that accurately predicts sorption in a given soil under a given set of conditions. This is especially true for ionic and polar molecules. Future research should be devoted to developing such models that require a minimum of measurement inputs.

Abstract

Oxanyons are negatively charged compounds composed of a central cation and oxygen ions. These species are ubiquitous in nature and are essential nutrients for plants but can also be harmful to organisms and the environment when their concentrations exceed critical levels. The sorption of oxanyons to solid soil components plays a crucial role in their fates in the environment, as it influences their mobility and availability. If oxanyons are retained weakly by soil particles, they can easily be desorbed and transported by the soil solution. Techniques such as ion-selective electrodes, colorimetry, and inductively coupled plasma-atomic emission spectrometry are essential for predicting their behavior in soil, which is critical for assessing environmental quality and developing effective management strategies.

Key points

- Oxanyons are prevalent in nature.
- Oxanyons can be toxic to organisms when their concentrations exceed critical levels.
- Sorption of oxanyons to solid soil components plays a critical role in their fate in the environment.
- The use of spectroscopic techniques is essential for understanding and predicting the behavior of oxanyons in soil.

Introduction

An oxanyon is a net negatively charged compound consisting of a cation at its center surrounded by oxygen ions. There are many different oxanyons present in soils. The most common ones of interest to soil and environmental scientists include phosphates (PO_4^{3-}), arsenite (AsO_3^{3-}), arsenate (AsO_4^{3-}), selenite (SeO_3^{2-}), selenate (SeO_4^{2-}), chromate (CrO_4^{2-}), molybdate (MoO_4^{2-}), carbonate (CO_3^{2-}), sulfate (SO_4^{2-}), nitrate (NO_3^-) and perchlorate (ClO_4^-). Oxanyons are prevalent in nature, and most of these are essential nutrients for plants. Almost all of them, however, are also toxic to plants and the environment when their concentrations rise above a certain critical level. For example, excessive amounts of some oxanyons, namely nitrates and phosphates, are directly responsible for the eutrophication of our ponds and lakes (Priya et al., 2022).

There are numerous other oxanyons that are discussed in the environmental literature, particularly in connection to industrial and nuclear waste disposal, or spills and remediation. Industrial oxanyon wastes include many of those already mentioned above. Radioactive waste and environmental studies may include oxanyons such as pertechnetate (TcO_4^-). No stable isotopes of Tc exist (which are prepared in very small amounts in cyclotrons) and because this radionuclide is rather dangerous to work with, a surrogate oxanyon is typically studied instead, namely perhenate (ReO_4^-).

The fate of oxanyons in soils in the environment depends strongly on their sorption to soil mineral components (Xinxin et al., 2021). That is, an oxanyon that is adsorbed to an immobile solid phase will not be transported to a new location, because movement of oxanyons in the environment is through the liquid phase. Retention by solids results in a longer availability of oxanyons in a defined area. For example, leaching from the soil's upper horizons down toward groundwater does not occur as long

as it is sorbed to the immobile solid phase. Lateral liquid movement to nearby streams is also minimized, as is its subsequent transport to larger bodies of water.

This assumes that the solid phase to which the oxyanion is sorbed is itself immobile. Keep in mind, however, that some solids (such as colloidal-sized particles) are very small and can be translocated by the moving water. This translocation of mobile solids together with the ions sorbed on to them can be vertically through soil horizons, horizontally with the groundwater flow, or as soil erosion moving horizontally over the soil surface (Hussain et al., 2021).

An understanding of the sorption of oxyanions to solid soil components is important for an evaluation of the quality of the environment. If the oxyanions are retained only weakly, then the moving water will easily remove them from the soil. If the retention of oxyanions by the immobile solid phase is moderate in strength, then the moving water will remove the oxyanions from the area slowly. Conversely, if the oxyanions are retained strongly by immobile solids, then the moving water will remove them from the area very slowly. If the solid phases are small enough to be mobilized by moving water, then attention to the turbidity of the liquid phase or the presence of surface soil erosion must be included in any evaluation of environmental quality. This is because the mobile solids typically will have sorbed contaminants on them.

Techniques for detection and quantification of oxyanions in solution

Quantitative studies of the adsorption of oxyanions on soils and minerals require determination of the oxyanion concentration remaining in the aqueous phase (Liang et al., 2021). That is, the amount adsorbed equals the amount of anion added to the solid-liquid suspension minus the amount remaining in the liquid phase at equilibria. Many different instruments can be used for the liquid-phase analysis, such as ion-selective electrodes, colorimetric methods, ion chromatography, atomic absorption, and inductively coupled plasma-atomic emission spectrometry. With some of these methods (namely, the first three mentioned), one must be particularly cautious to avoid problems attributed to speciation and complexation interferences. These complications can usually be avoided by measuring the liquid phase concentration with a high background ionic strength and at a specified pH condition. One does not generally quantify the number of oxyanions adsorbed by direct measurement of the solid-phase concentration. This is because many of the solid phase measuring methods require expensive instruments and/or the quantitative precision is not satisfactory.

Techniques for investigation of oxyanions adsorbed at mineral–water interfaces

Various surface-sensitive techniques have been used to obtain structural information of surfaces and surface species that are needed to identify adsorption mechanisms and reactions. An important aspect of the application of spectroscopic techniques to the investigation of adsorbed species is the experimental conditions under which the spectra of the sample are collected. Invasive or ex situ methods commonly require extensive sample desiccation in a vacuum, which have the potential to modify or destroy sorption complexes usually present at the solid–liquid interface in an aqueous environment. Conversely, noninvasive or in situ methods require little or no alteration of a sample from its natural state. Clearly, to resolve the structure of surface species present at a mineral–water interface of natural particles, in situ spectroscopic techniques are required that can be applied in the presence of liquid water (Savoye et al., 2021). Three examples of in situ techniques that have been used to investigate oxyanions on mineral–water interfaces are attenuated total reflectance–Fourier-transformed infrared (ATR–FTIR), Raman, and X-ray absorption spectroscopy (XAS). A brief overview of these techniques is given below.

The predominant aim of spectroscopic analysis of adsorbed oxyanions at the solid–liquid interface is to understand the symmetry and binding mechanism of the anion on the surface. Quantitative measurements (“How many ions are adsorbed?”) are not the primary focus because, as was noted above, this is much more easily determined based on mass balance of the elements added and recovered from the liquid phase. Spectroscopy is the only method, however, that can determine how the ions are held on the surface. Fig. 1 shows five commonly encountered possibilities. Using selenite as the example oxyanion, it can be held as an outer sphere (Fig. 1A), where at least one molecule of water exists between the anion and the surface. It may be embedded in the internal regions of the mineral (Fig. 1B) due to solid diffusion of the anion into the mineral or to some coprecipitation of the anion with a cation onto the surface of the mineral. Fig. 1C–E shows the anion held as an inner sphere, where the anion bonds directly with the mineral surface. An inner-sphere anion can be monodentate (Fig. 1D) or bidentate (Fig. 1C and E). ‘Monodentate’ means that only one bond is formed between the anion and the surface, whereas ‘bidentate’ means that two bonds are formed between the anion and the surface. The bidentate inner-sphere bonds can be mononuclear (Fig. 1C) or binuclear (Fig. 1E), which refer to the minimum number of mineral cations that are required to link the anion’s oxygen ions to the mineral.

Vibrational spectroscopies

Vibrational spectroscopic techniques such as FTIR and Raman spectroscopy probe the vibrational properties of molecules (Sun and Doner, 1996). Characteristic vibrational properties of oxyanions originate from X–O(H) stretching and bending vibrations. Each oxyanion has its characteristic pattern of vibrations that relates to its symmetry state. The symmetry, and consequently the vibration pattern, changes when an oxyanion complexes with other ions such as protons or metal cations. Changes in the number and

Fig. 1 Schematic diagram of several possible geometric arrangements of an oxyanion at the solid–water interface. Selenite is the adsorbate oxyanion and an iron oxide the adsorbent mineral. The area above each surface (indicated by solid horizontal lines) is water, and the solid mineral phases are below the solid horizontal lines. Reprinted from Brown GE Jr, Parks GA, and Chisholm-Brause CJ (1989) In-situ X-ray absorption spectroscopy studies of ions at oxide–water interfaces. *Chimia* 43: 248–256.

position of the vibrational bands provide information about the speciation and coordination state of the oxyanion. This behavior is the underlying principle of the determination of the types of surface species using vibrational spectroscopy.

Spectra of outer-sphere complexes are similar to the spectra of the free anion in solution. Differences in position and number of adsorption bands between the spectra of solution and adsorbed species indicate coordination with the surface, that is, inner-sphere complexation. Determination of the coordination state of an inner-sphere complex (mono- or bi-dentate and mono- or bi-nuclear) is usually based on the comparison of spectra of adsorbed species with data from the literature of spectra of coordinated compounds with known structures. Extensive infrared and Raman spectral data of inorganic and coordination compounds are available.

Attenuated total reflectance–Fourier-transformed infrared (ATR–FTIR) spectroscopy is an in situ, infrared sampling technique that can provide information about surface species at the mineral–water interface. Note that, since water strongly adsorbs infrared, it was the introduction of ATR (and other similar detection modifications, such as cylindrical internal reflectance, CIR) that has given us the necessary breakthrough to use FTIR effectively in aqueous (i.e., natural) media. This technique has been applied successfully to investigate various anions (PO_4^{3-} , $\text{B}(\text{OH})_4^-$, SO_4^{2-} , CO_3^{2-} , NO_3^-) at metal oxide–solution interfaces (Bowmaker et al., 2005).

The use of ATR–FTIR does not fully avoid water absorption of the infrared signal. The spectral window in metal oxide aqueous suspensions is limited by the strong adsorption by water and metal oxide lattice vibrations in the region below 1000 cm^{-1} and the strong adsorption by water in the region of $3000\text{--}4000\text{ cm}^{-1}$. For example, vibrations of the oxyanions of Se and As are expected below 1000 cm^{-1} and, consequently, are difficult to observe in these systems with the ATR–FTIR technique.

Diffuse reflectance FTIR (DRIFT) is an infrared sampling technique that requires air-drying of the sample. In general, this does not greatly affect the surface speciation and coordination of the adsorbed oxyanion because a very thin layer of water should remain on the mineral surface. Because there is less interference with the strong absorbing of water, this sampling technique enables the investigation of OH-stretching in the spectral range of $3400\text{--}3800\text{ cm}^{-1}$. The OH-stretching bands can provide information about the effect of oxyanion adsorption on the surface OH groups of the mineral surface.

Raman spectroscopy can provide a window in the spectral region below 1000 cm^{-1} to investigate aqueous minerals and, accordingly, can provide complementary data to IR spectroscopy (Dobrea et al., 2015; Nakamoto, 2009). One of the attractive aspects of Raman spectroscopy to minerals in aqueous suspension is that it is transparent to water, which makes in situ investigation of surface species possible. The recent advances in Raman instrumentation have brought new opportunities for applications to investigate surface species at mineral–water interfaces. Raman spectroscopy has been used to study the interfacial species on metal oxides of SeO_4^{2-} , SO_4^{2-} , AsO_4^{3-} and AsO_3^{3-} .

X-Ray absorption spectroscopy

X-ray absorption spectroscopy (XAS) is another technique that can be applied to in situ studies of adsorbates at mineral–water interfaces (Fendorf et al., 1997). It is an element-specific, short-range probe that provides information about the local structural and compositional environment of an adsorbing atom. X-ray absorption near-edge structure (XANES) spectra provide information about the bonding and oxidation state of the adsorbing atom. Extended X-ray absorption fine structure (EXAFS) can provide information about the composition and structure in the vicinity of the element. The absence of back-scattering beyond the first shell indicates an outer-sphere complex. In the case of inner-sphere complexes, the number, distance, and type of back-scatterers provide information for identifying the type of inner-sphere complex (mono-versus bidentate). X-ray absorption spectroscopy has been used to identify the adsorption mechanisms of the oxyanions of Se, As, and Cr (Bullen et al., 2022). The technique requires high-energy X-rays, which are only available at synchrotron facilities.

Sorption strength of oxyanions

The strength of the bond of oxyanions with mineral surfaces strongly affects the fate of the oxyanion in the environment. Weakly held anions leach easily and are lost from the upper soil horizons down toward the groundwater or are readily carried in surface runoff to nearby streams. There are a few ways to determine the relative strength of these bonds. One common method involves adsorption isotherms, and another involves adsorption edges.

An adsorption isotherm analysis is based on measuring the amount of anion adsorbed by a solid phase as a function of the equilibrium concentration present in the liquid phase, as shown in Fig. 2 for sulfate adsorption onto an aluminum oxide (Wijnja and Schulthess, 2000). The curvature of the isotherm, which is particularly visible at low aqueous concentrations, is a function of the adsorption strength. Qualitatively, the sharper are the rate of increase and amount of curvature observed in the adsorption isotherm, the stronger is the adsorption strength of the compound with the surface. It is the curvature of the adsorption isotherm, not the adsorption maximum that indicates the strength of adsorption.

Efforts to quantify adsorption strength have been the focus of much debate in the literature for almost a century. For example, if we assume a simple adsorption mechanism:

then the amount adsorbed can be predicted mathematically using data-fitting techniques with the Langmuir isotherm equation:

$$\text{Amount Adsorbed} = MKc/(1 + Kc) \quad (2)$$

where M is the maximum adsorption, which can be obtained from the isotherm at large aqueous concentrations; K is the Langmuir constant, which is equal to the ratio P/R , with P the adsorbed anion concentration, R the (concentration of unoccupied surface

Fig. 2 Adsorption isotherms of sulfate on an aluminum oxide (bayerite). Notice that the presence of carbonates increased the adsorption strength of sulfate, which is contrary to the competitive adsorption behavior typically observed when two adsorbing anions are in solution. Reprinted from Wijnja H and Schulthess CP (2000) Interaction of carbonate and organic anions with sulfate and selenate adsorption on an aluminum oxide. *Soil Science Society of America Journal* 64: 898–908.

Fig. 3 Adsorption envelopes (adsorption as a function of pH) for various oxyanions on goethite: (A) adsorption of carbonate. Notice the competitive behavior of selenate on carbonate adsorption; (B, C) adsorption of selenate in the presence of carbonate and acetate. Notice the enhancement by these oxyanions of selenate adsorption. sites) $\times$ (aqueous anion concentration); and c is the aqueous anion concentration at reaction equilibria. The adsorption strength is quantified here by the Langmuir constant, K . There is considerable debate, however, about how the adsorption mechanism should be modeled; that is, modeling the adsorption reaction by Eq. (1) and other similar equations is not yet fully validated. Note that a model that does not fit the data is clearly invalid. However, a model that does fit the data is not necessarily automatically adequately validated.

One can also infer the relative strength of an adsorbing anion based on the pH value of the adsorption edge, which is shown in Fig. 3 (Wijnja and Schulthess, 2002). For a given mixture, the amount of aqueous anion adsorbed by the solid phase depends strongly on the equilibrium pH of the system. Working through the pH scale, first there is no adsorption of anions at high pH values. At intermediate pH values, there is an abrupt increase in adsorption. The pH value measured at the midpoint of this abrupt increase in adsorption is the pH value of the adsorption edge. At much lower pH values, there is a decrease in the number of anions adsorbed. The entire bell-shaped curve is known as an adsorption envelope.

If we assume that the adsorption mechanism involves the co-adsorption of hydroxyl anions (OH^-), for example:

then we can use the pH value of the adsorption edge to compare the relative adsorption strength of the anion. At equimolar concentrations, the anion that has a larger adsorption edge value is the one that binds more strongly with the surface. Notice in Eq. (3) that a strong surface–anion bond will require a greater concentration of OH^- anions to reverse the reaction. The midpoint of

equilibria for Eq. (3) occurs at the adsorption edge. Accordingly, if the adsorption of an anion is strong, then the number of OH^- anions needed to reverse the reaction will be large, and the pH value of the adsorption edge will also be high.

Efforts to quantify the adsorption strength based on the pH value of the adsorption edge are not yet fully resolved. The problem arises because we are not sure that Eq. (3) or other similar equations fully describe the adsorption process. Consequently, the mathematical interpretation of pH-dependent data is still discussed extensively in soil science research articles. In addition, it is noted that while some progress has been made in comprehending the adsorption of oxanions on mineral surfaces, there are still gaps that are not fully addressed. Ongoing research is needed to perceive fully the underlying mechanisms and to develop accurate models that can predict the adsorption behavior of different oxanions under different conditions. We do know, however, that if the pH is kept constant, then Eq. (3) will simplify to Eq. (1), and equations similar to Eq. (3) will simplify to equations similar to Eq. (1). We also know that anion adsorption involves the release of hydroxyl anions. Note that it is difficult to distinguish hydroxyl release (which chemically removes protons from solution) from proton coadsorption (which physically removes protons from solution). Accordingly, essentially identical concepts can be presented using equations that illustrate proton co-adsorption to the surface rather than hydroxyl release from the surface.

With the tools outlined above, a general review of the published data suggests the following trend: the larger is the negative charge present on the oxyanion, the stronger is the affinity of the oxyanion toward the surface. Within each group, there is much uncertainty about which is more strongly adsorbed, and this is probably due to numerous reasons (such as, presence of surface contaminants). In general, the affinity of trivalent oxanions follows the sequence: $\text{AsO}_3^{3-} > \text{PO}_4^{3-} \approx \text{AsO}_4^{3-}$. Divalent oxanions adsorb more weakly, and in general follow the affinity sequence $\text{SeO}_4^{2-} > \text{CrO}_4^{2-} > \text{CO}_3^{2-} > \text{SeO}_3^{2-} \approx \text{SO}_4^{2-} > \text{MoO}_4^{2-}$. Monovalent oxanions such as ReO_4^- , NO_3^- and ClO_4^- , are very weakly adsorbed. Another, more useful observation is the close correlation of adsorption affinities of oxanions with the stability constants (pK_a values) of their conjugate acids; noteworthy is the high adsorption affinity of $\text{B}(\text{OH})_4^-$ by minerals. For these reasons, nitrates or perchlorates are sometimes used as background electrolytes in adsorption studies and are often assumed not to adsorb at all or to cause no significant effect on the adsorption process of the other compounds present.

Effect of ions on adsorption of oxanions

The presence of dissolved electrolytes in the mixture affects the adsorption of oxanions (Li et al., 2022; Rietra et al., 2000). Adsorption studies, therefore, are pursued under constant ionic-strength conditions. These background electrolytes consist of dissolved cations and anions such as Na^+Cl^- or Na^+NO_3^- . It is critical to the adsorption study that the reactivity of these ions with the surface be minimal, preferably completely unreactive, or at least constant in their reactivity. Sometimes, an aqueous phase complexation reaction occurs between the oxyanion being studied and the components of the background electrolyte. This will complicate the analysis and should be avoided as much as possible, preferably by using a different background electrolyte.

The presence of dissolved electrolytes affects the adsorption process in numerous ways. First, it raises the ionic strength of the solution. This tends to decrease the electrostatic attraction of the adsorbate due to the lowering of surface potential or the masking of the surface charge. This effect on the adsorption process is not serious provided that the ionic strength remains constant throughout the study.

Second, the background anion can compete with the oxyanion for adsorption sites, which is very likely at high ionic-strength concentrations. Although adsorption of the background anion (e.g., Cl^-) is typically extremely weak, it is rarely zero and its competitive effect increases significantly as its concentration in solution increases (Schulthess and Hu, 2001). This effect on the adsorption process is not serious as long as the concentration of background ions is kept constant. It will, however, cause some complications to attempt to understand or quantify the adsorption strength of the oxyanion. When comparing adsorption isotherms or adsorption edges of adsorption envelopes, it is beneficial if the oxanions are compared at the same ionic strength and initial conditions. This effect is shown in Fig. 3A at low pH, where the concentration of weakly competitive aqueous Cl^- anions has increased to the point of rendering it significantly competitive with the carbonate oxyanion. The source of the Cl^- anion at low pH is from the addition of acids (namely, HCl) needed to achieve the low-pH conditions (Schulthess and Sparks, 1991).

Competition between anions is also shown in Fig. 3A, where the presence of selenate significantly reduces the adsorption of carbonate. Competition between oxanions is commonly observed. Competitive behavior should be expected because of the structural similarities of the oxanions and the similarity of their adsorption sites (Tahmasebi, 2020). Large Cl^- concentrations will also decrease the amount adsorbed over a broad pH range due to competitive adsorption.

Third, reactivity of the background anion (e.g., Cl^-) with the surface may be pH-dependent. Note that the first two problems mentioned above assume, for simplicity, that the reactivity of the background anion is pH independent. However, this is perhaps one of the most serious problems that can arise in the study of oxyanion-adsorption processes. In these situations, reactivity of the background anion must be monitored if the adsorption reactivity of the oxyanion with the solid surface is to be properly understood.

Fourth, some anions may be present in the mixture that enhance the adsorption reaction of the aqueous oxyanion with the solid surface. Note that this is a counterintuitive process because traditional views do not include an anion that causes an increase in adsorption of another similarly charged ion. Fig. 2 shows a sharp increase in adsorption of sulfate on an aluminum oxide in the presence of carbonate. Fig. 3B and C shows that this enhancing effect is also pH-dependent (Wijnja and Schulthess, 2002). The enhancement of oxyanion adsorption, such as sulfate and selenate adsorption on aluminum and iron oxides, has been observed in

Fig. 4 Adsorption of 1 mM selenate at pH 6.8 on an aluminum oxide (bayerite) as a function of the amount of carbonate added. Notice that the presence of carbonates increases the adsorption of selenate at low carbonate concentrations. Reprinted from Wijnja H and Schulthess CP (2000) Interaction of carbonate and organic anions with sulfate and selenate adsorption on an aluminum oxide. *Soil Science Society of America Journal* 64: 898–908.

the presence of carbonates, acetate, and formate anions. At large concentrations, these anions seem to become competitive. Hence, an enhancing effect does not exclude the existence of a concurrent competitive effect. The enhancing effect is most pronounced at small concentrations, where any possible competitive effect would also be at its lowest level (Fig. 4) (Wijnja and Schulthess, 2000). It is not clear how prevalent the enhancing effect is in nature or in laboratory studies. The co-adsorption effect, where the presence of certain anions enhances the adsorption of other oxyanions to solid surfaces, is a topic of ongoing research. Studies have demonstrated this effect in various systems, but the underlying mechanisms and prevalence in natural systems are not fully understood. Further research is needed to comprehend fully the implications of the co-adsorption effect on the fate and transport of oxyanions in the environment. We do know, however, that carbonates are nearly always present in aquatic systems. Their concentration in laboratory solutions varies widely depending on the purity of water sources used or on the techniques used to minimize or control the carbonate concentrations. In other words, aqueous carbonate impurities can easily enter sample preparations unbeknown to the experimenters and cause a wide range in the variance of the data collected. This creates a serious problem for those that wish to understand and quantify the adsorption of oxyanions by solid surfaces in aqueous media.

Sorption mechanisms of oxyanions

The adsorption reaction of oxyanions at a mineral surface is described as a surface complexation reaction between the oxyanion and a surface functional group forming a surface complex. With respect to the types of surface complexes or adsorption mechanisms, there are commonly two major types distinguished: inner-sphere and outer-sphere complexes. An inner-sphere complex is formed by a ligand-exchange reaction with a surface-OH or surface -OH^+_2 group and is directly coordinated with the underlying surface metal ion. In a monodentate inner-sphere complex, one bond is formed with a surface group. In a bidentate complex, two bonds are formed, either with one surface metal ion (mononuclear) or with two surface metal ions (binuclear). In contrast, outer-sphere complexes form mainly by electrostatic interactions and at least one water molecule is interposed between the oxyanion and the mineral surface. Diffuse-swarm ions do not form a complex with a surface functional group, but are bound only through electrostatic interactions that neutralize the surface charge (Zheng et al., 2020). Diffuse-swarm is a specific type of adsorption mechanism where the anion does not form a complex with the surface functional group, but instead is bound only through electrostatic interactions that neutralize the surface charge (McBride, 1994). Spectroscopic tools are essential for the development of detailed descriptions of the adsorbed oxyanion. A mechanistic description of the adsorption process requires spectroscopic information of the adsorbed species, information on the stoichiometry of the reaction and rates of reaction, and a measure of the strength of adsorption.

Oxyanions with a relatively strong adsorption affinity such as PO_4^{3-} , AsO_4^{3-} , SeO_4^{2-} and B(OH)_4^- form predominantly inner-sphere complexes on metal oxide surfaces. Both monodentate and bidentate complexes have been found on metal oxides for several of these oxyanions (Lepore et al., 2022). For example, it has been shown that the relative distribution of monodentate and bidentate inner-sphere complexes of AsO_4^{3-} and CrO_4^{2-} varies with the surface coverage.

The CO_3^{2-} anion forms monodentate inner-sphere complexes at metal oxide–water interfaces. Oxyanions with weak affinity, such as NO_3^- and ClO_4^- adsorb mainly as outer-sphere and diffuse-swarm ions.

Several anions that have high or moderate sorption affinity, such as AsO_4^{3-} , SeO_4^{2-} and SO_4^{2-} , show intermediate behavior, where both inner- and outer-sphere surface complexes coexist at metal oxide–water interfaces. For these moderately adsorbing anions, the relative distribution of inner- versus outer-sphere adsorption depends on pH, ionic strength, and type of mineral.

When an anion is held as an inner-sphere compound, then it has probably been preceded by an initial outer-sphere attraction to the mineral surface (Tahmasebi, 2020). The mechanism of forming an inner-sphere bond must involve the release of a molecule of water from the solid–liquid interface into the bulk solution. A net volume change occurs to the system whenever this process occurs, and this can be measured with a dilatometer. Based on measured volume changes, there is approximately one molecule of H_2O released into the bulk solution for every aqueous molecule of SO_4^{2-} , SeO_4^{2-} , or H_2PO_4^- adsorbed onto an amorphous iron hydroxide at pH 4.5, which should be expected for inner-sphere adsorption of these oxyanions (Yamaguchi et al., 1999).

Anion adsorption is accompanied by proton uptake. The net proton uptake is the result of a ligand exchange reaction (OH release), surface protonation, oxyanion protonation on the surface, or a combination of these. Quantifying the number of protons co-adsorbed (or OH released) by the surface per molecule of oxyanion adsorbed is an important component of our understanding of the adsorption process. This stoichiometry of the reaction directly affects how the surface reaction will be described, such as the 1:1 stoichiometry described in Eq. (3). This, in turn, also affects how the surface complexation model will be developed. The best way to obtain data on the adsorption or co-adsorption of protons is by an acid–base titration method known as the backtitration technique (Schulthess and Sparks, 1986).

Anion adsorption affects the electrostatic properties of mineral surfaces. The net surface charge of a mineral surface is the result of proton-transfer reactions and surface-complexation reactions. Electrophoretic mobility measurements can reveal the net changes in surface charge due to oxyanion adsorption. In general, the adsorption of an oxyanion tends to lower the positive charge present on a surface. The positively charged surface does not necessarily become negatively charged following the adsorption of oxyanions. Rather, it tends to approach a net neutral surface charge. Taking these data in conjunction with the proton co-adsorption data mentioned above, the adsorption of oxyanions and proton co-adsorption tends to form net neutral products on the mineral surfaces.

The adsorption of oxyanions generally reaches a maximum at around the pK_a value for the conjugate Bronsted acid, as shown in Fig. 3A for carbonate adsorption ($\text{pK}_a = 6.3$). One can generally infer that the higher is the value of the oxyanion's acidity constant (pK_a), the stronger will be its adsorption by a hydrophilic surface. This further reflects the importance of the co-adsorption of protons on the adsorption mechanism of oxyanions (Figueiredo and Quintelas, 2014). The mechanism of bringing the co-adsorbed protons to the mineral surface does not necessarily follow a separate, independent path from that taken by the adsorbing oxyanion. The proton can be brought toward the mineral surface by the protonated oxyanions. The fate of the co-adsorbed proton may be: (1) to remain complexed with the adsorbed oxyanion (hence, the oxyanion is held as a Bronsted acid on the mineral surface); (2) to remain complexed with the surface (hence, the oxyanion's negative charge is neutralized by a positively charged surface–surface, which may or may not be directly below or adjacent to the adsorbing oxyanion); or (3) it may react with a surface-OH group and form an H_2O product that diffuses back to the bulk solution (this may also be described schematically as a hydroxyl exchange mechanism, where the hydroxyl is neutralized by free protons in the aqueous phase).

Site preference and site reactivity

Surface hydroxyl groups constitute the complexation sites on metal oxide surfaces suspended in aqueous solutions. The surface groups behave as weak Bronsted acids or bases, capable of ionizing to yield a pH-dependent charged surface or serving as a ligand in surface complexation reactions. Analysis of the crystal structure of metal oxides indicates the existence of various types of surface hydroxyl groups with different reactivities. Their reactivity depends, among other factors, on their coordination environment (singly, doubly, and triply metal-coordinated). The different crystal planes of a metal oxide mineral have a different composition with respect to the types of surface groups and densities of these groups.

With respect to complexation of oxyanions, the singly coordinated surface hydroxyls are known to be most reactive. Recent studies have used advanced techniques such as XAS and FTIR to provide more detailed information on the structure of adsorbed oxyanions at mineral–water interfaces, which can provide new insights into the complexation mechanisms (Tamijani et al., 2020). An FTIR study on the effect of As oxyanions on the various types of surface groups has indicated that the singly coordinated surface groups are involved in the ligand exchange reaction to form inner-sphere complexes (Manning et al., 1998).

There are several things that the adsorbed oxyanion can do after it has adsorbed to the mineral surface. It can desorb from the surface and diffuse back to the aqueous bulk solution. Given the high energy of hydration of many of these oxyanions, this desorption step is very likely and is the basis for establishing the equilibrium condition where only a specific density of anions remain adsorbed to the surface for a given concentration of anions in solution.

The adsorbed oxyanion can also diffuse into the mineral through a process known as solid diffusion (product is shown in Fig. 1B). Solid diffusion at ambient temperatures is a very slow process. However, the oxyanion may also become entrapped inside the mineral through the process of oxyanion-enhanced dissolution of the mineral followed by co-precipitation of the oxyanion–metal complex.

A final option for the adsorbed oxyanion is to migrate laterally, traveling horizontally on the mineral surface along a two-dimensional matrix. This depends on the strength of the bond of the oxyanion with the surface. The lateral, two-dimensional

mobility of the oxyanion allows it to migrate toward a more stable adsorption site (more stable, that is, relative to its point of initial collision and reaction with the surface). Lateral mobility of adsorbed ions is known to occur on solid–gas interfaces, but data are missing that quantify accurately this mobility on solid–liquid interfaces.

Conclusions

Adsorption of oxyanions to mineral–water interfaces plays a crucial role in determining their fate in the environment. A variety of techniques such as ATR–FTIR, Raman and XAS have been used to study the structural information of surfaces and surface species, and in situ methods are preferred because they require little or no alteration of the sample from its natural state. It has been determined that oxyanions with a high adsorption affinity, such as PO_3^{4-} , AsO_3^{3-} , SeO_2^{3-} and $\text{B}(\text{OH})_4^-$, form predominantly inner-sphere complexes on metal oxide surfaces. In contrast, oxyanions with low affinity, such as NO_3^- and ClO_4^- , mainly form outer-sphere and diffuse-swarm ions. The adsorption strength of oxyanions can be quantified by methods such as the Langmuir isotherm equation and pH value of the adsorption edge. However, the mechanism of adsorption is still debated, and further research is needed to understand fully the process. Overall, understanding the adsorption of oxyanions to mineral–water interfaces is crucial for assessing soil and environmental quality, and for developing effective management strategies.

Abstract

Sorption of metals at the solid–solution interfaces of soil minerals and soil organic matter is an important process for metal retention and release in soils. Sorption reactions include inner-sphere and outer-sphere adsorption complexation, and surface precipitation. This chapter discusses different metal sorption reaction processes and the soil properties that influence them.

Key points

- Metals adsorb on soil mineral and organic matter surfaces via outer-sphere and inner-sphere complexation.
- Metals can form multinuclear precipitates on soil mineral surfaces.
- Multiple metal sorption mechanisms can occur within the same soil.
- Sorption mechanism depends on soil pH, ionic strength, and soil composition.

Introduction

The sorption (retention) of metals, including alkali, alkaline earth, transition, and other metals (e.g., Pb^{2+}) on soil mineral and organic constituents is one of the most important processes controlling their fate, transport, and bioavailability in soil and water environments (McKenzie, 1980; Sumner, 1998; Sauve et al., 2000; Sparks, 2002; Strawn et al., 2020). This chapter discusses the terminology for sorption processes, the role of surface functional groups on mineral and organic soil components in metal sorption, the types of surface complexes in soils that metals form, and the importance of surface precipitation reactions in sequestering metals in soils.

Terminology and role of sorption processes in soils

Adsorption and surface precipitation are examples of sorption—a general term that is used when the retention mechanism of a chemical on a surface is not specified. Adsorption is a type of sorption process describing the accumulation of a substance or material at an interface between the solid surface and the bathing solution. Adsorption describes the removal of chemicals from solution (solute) and attachment to surfaces as a separate phase from the solid. Adsorption does not include surface precipitation, which is the formation of a three-dimensional phase on a surface, or polymerization of small multinuclear inorganic species on mineral surfaces.

There are various metal sorption mechanisms that can occur at soil mineral surfaces that involve both physical and chemical processes (Fig. 1) (Sposito, 1987; Hiemstra et al., 1989; Goldberg, 1992). Some general terms that describe adsorption reaction processes are as follows: the solid surface is referred to as the adsorbent; the ion in solution that has the potential of being adsorbed is the adsorptive; and the material accumulated on a surface is the adsorbate. If the general term *sorption* is used, the material that accumulates at the surface, the solid surface, and the ion in solution are referred to as sorbate, sorbent, and sorptive, respectively.

Adsorption is one of the most important chemical processes in soils. It determines the quantity of plant nutrients, metals, pesticides, and other organic chemicals that are retained on soil surfaces, and therefore is one of the primary processes affecting

Fig. 1 Illustrations of sorption mechanisms on a metal oxide mineral surface.

transport of both nutrients and contaminants in soils. Adsorption also affects the electrostatic properties of particles in soils, e.g., coagulation and settling of suspended colloids.

Adsorption involves three types of interactions: (1) electrostatic interactions, including van der Waals forces (e.g., adsorption partitioning of uncharged solutes), (2) electrostatic outer-sphere complexes (e.g., ion exchange), and (3) formation of chemical bonds (Sposito, 1981; Bolt and Van Riemsdijk, 1979; Evangelou and Phillips, 2005). Chemical bonds are short-range molecular interactions, referred to as inner-sphere complexation, which involves covalent and ionic bonding between the ligand functional groups on soil mineral or organic matter surfaces and ions or uncharged chemicals that occur on the mineral surfaces (sorbate) (Bolt and Van Riemsdijk, 1979; Forbes et al., 1976; Goldberg, 1992).

Properties of metals

Metals occur in the environment in many species, including oxyanions (e.g., CrO_4^{2-}), hydrolysis complexes (e.g., NiOH^+), and hydrated cations (e.g., $\text{Na}^+(\text{H}_2\text{O})_6$ and $\text{Zn}^{2+}(\text{H}_2\text{O})_6$). Table 1 lists metals that are often of concern in the environment and their typical concentrations in soils. Other metals not listed in Table 1, such as rare earth elements and lanthanides and actinides, are of concern in some environments; for example, areas impacted by nuclear waste disposal. The sorption characteristics of metals depend on their ability to share electrons, their oxidation state, and their ionic size. Valence and ionic radius can be combined to calculate the ionic potential. For example, Mg^{2+} has a charge of two plus and a relatively small ionic radius, so has a large ionic potential that strongly attracts the partial negatively charged oxygen in water molecules. The result is the Mg^{2+} cation has a relatively strong or large hydration sphere that is maintained during adsorption as an outer-sphere complex. Other metals, such as Cu^{2+} or Pb^{2+} , have electron orbital vacancies that can be shared with the electrons of ligands on mineral and organic matter surfaces forming covalent bonds, which are called inner-sphere complexes (Strawn and Sparks, 1999).

Surface characteristics

Another important consideration in metal sorption mechanisms are the properties of the soil particle surfaces. Some minerals, such as clays, have permanently charged surfaces that do not change charge magnitude or sign with changes in pH. Variable charged mineral surfaces have functional groups in which the charge magnitude and sign change as pH changes because of protonation and deprotonation of the acidic surface functional groups. The type of interaction of functional groups with adsorptive ions depends on the characteristics of the surface functional groups (i.e., acidity and molecular coordination to the mineral cations) (Kubicki et al., 2008), and the properties of the adsorptive ions.

Permanent charge minerals

Clay minerals in soils have permanent negative charges on their interlayer surfaces created from isomorphous substitution (Sumner, 1998; Strawn, 2021). Cations are attracted to the negatively charged interlayers through electrostatic forces. Most cations maintain

Table 1 Oxidation states and concentration of important metals in soils. Values are from Bowen (1979).

Element	Oxidation states	Range (mg kg ⁻¹)	Median
<i>Alkali metals</i>			
Sodium	Na ⁺	150–25,000	5000
Potassium	K ⁺	80–37,000	14,000
Cesium	Cs ⁺	0.3–20	4
<i>Alkaline earth metals</i>			
Magnesium	Mg ²⁺	400–9000	5000
Calcium	Ca ²⁺	700–500,000	15,000
Strontium	Sr ²⁺	4–2000	250
Barium	Ba ²⁺	100–3000	500
<i>Transition metals</i>			
Vanadium	V ^{5+a}	3–500	90
Cobalt	Co ²⁺	0.05–65	8
Chromium	Cr ^{6+a} , Cr ³⁺	5–1500	70
Molybdenum	Mo ^{6+a}	0.1–40	1.2
Manganese	Mn ⁴⁺ , Mn ²⁺	20–10,000	1000
Iron	Fe ³⁺ , Fe ²⁺	2000–550,000	40,000
Nickel	Ni ²⁺	2–750	50
Copper	Cu ²⁺	2–250	30
Zinc	Zn ²⁺	1–900	90
Cadmium	Cd ²⁺	0.01–2	0.4
Mercury	Hg ²⁺ , Hg ¹⁺ , Hg ⁰	0.01–0.5	0.06
<i>Other metals</i>			
Aluminum	Al ³⁺	10,000–300,000	71,000
Lead	Pb ⁴⁺ , Pb ²⁺	2–300	35

^aSpecies occurs as oxyanion.**Fig. 2** Metal adsorption in the interlayer of a clay mineral as a hydrated exchangeable cation. Adapted from Strawn D, Bohn HL and O'Connor GA (2020) *Soil Chemistry*, John Wiley & Sons: Hoboken, NJ, with permission.

their hydration sphere in the interlayer of the clays; K⁺ and Cs⁺ are exceptions because they have large ionic radii with low ionic potential and thus dehydrate and fit perfectly in the clay mineral structure becoming fixed in the interlayer. Hydrated metals adsorbed in the interlayer of clays are exchangeable, and referred to as exchangeable cations, which comprises the soil's cation exchange capacity (CEC) (Fig. 2) (Sposito, 1981).

Surface functional groups

Surface functional groups in soils play a significant role in adsorption processes (Anderson and Sposito, 1992; Chorover and Sposito, 1995; Goldberg, 1992; Hiemstra et al., 1989; Tournassat et al., 2016; Uehara and Gillman, 1980). A surface functional group is a chemically reactive molecular unit attached at the boundary of a solid with the reactive groups exposed to the soil solution. Surface functional groups can be organic (e.g., carboxyl, carbonyl, phenolic) or inorganic molecular units. The major inorganic surface functional groups in soils are hydroxyl groups that are associated with the edges of minerals such as kaolinite, amorphous materials such as allophane and ferrihydrite, and metal oxides, oxyhydroxides, and hydroxides such as goethite, hematite, and gibbsite. Minerals with reactive surface functional groups occur in all soils, but are especially important in highly-weathered soils.

Surface complexation

When a metal is adsorbed on a mineral or organic matter surface functional group, it is called a surface complex. The overall reaction is referred to as surface complexation. There are two types of surface complexes that can form: outer-sphere and inner-sphere (Fig. 1) (Strawn and Sparks, 1999). If a water molecule is present between the surface functional group and the bound ion or molecule, the surface complex is termed outer-sphere. If there is not a water molecule present between the ion or molecule and the surface functional group to which it is bound, this is an inner-sphere complex. Inner-sphere complexes can be monodentate (metal is bonded to only one oxygen) and bidentate (metal is bonded to two oxygens).

Outer-sphere complexes involve electrostatic coulombic interactions and are thus weak compared to inner-sphere complexes, where the metals are bound through covalent or ionic bonds. Outer-sphere complexation, also called cation exchange, is usually a rapid process that is reversible. Outer-sphere complexation occurs on surfaces that are of opposite charge to the adsorbate.

Inner-sphere complexation may be a slower reaction than outer-sphere complexation, and is sometimes irreversible (Selim and Sparks, 2001). Inner-sphere complexation changes the overall surface charge because the metal charge is added to the intrinsic surface charge. Surface charge affects the sorption process through electrostatic attraction and repulsion forces between the surface and the metal cations in solutions. Outer- and inner-sphere complexation can occur simultaneously on some mineral surfaces.

In recent decades, molecular-scale analytical techniques such as X-ray absorption fine-structure spectroscopy (XAFS) and Fourier transform infrared spectroscopy (FTIR) have been employed to determine the type of metal surface complexes and products that form on soil surfaces. These techniques are advantageous because they can analyze systems under natural conditions where water is present. Based on these studies, it is observed that many metals, such as transition metals and Pb primarily form inner-sphere complexes, while strongly hydrated alkali and alkaline earth metals form outer-sphere complexes. At higher metal loadings and pHs, sorption of metals such as Co, Cr, Ni, and Zn on phyllosilicates and metal hydr(oxides) can result in the formation of surface precipitates (Corey, 1980; Siebecker et al., 2018). Thus, environmental factors such as pH, surface loading, ionic strength, type of sorbent, and time all affect the type of sorption complex or product. An example of this is shown for Pb sorption on montmorillonite at ionic strengths (I) of 0.006 and 0.1 and a pH range of 4–8 (Fig. 3) (Strawn and Sparks, 1999). With XAFS analysis, it was determined that at a pH of 4.48 and an I of 0.006 outer-sphere complexation on basal planes in the interlayer regions of the montmorillonite predominated. At a pH of 6.77 and I of 0.1, inner-sphere complexation on edge sites of montmorillonite was most prominent, and at pH of 6.76, I of 0.006 and pH of 6.31, I of 0.1, both inner- and outer-sphere complexation occurred. These data show that there is a continuum of adsorption complexes that can exist in soils.

pH and ion selectivity effects on metal sorption

Sorption of metal cations on variable charged surfaces is pH-dependent and is characterized by a narrow pH range where sorption increases to nearly 100%, traditionally known as an adsorption edge (Fig. 4) (Harter, 1983; Sauve et al., 2000). The pH position of the adsorption edge for a particular metal cation is related to its hydrolysis or acid–base characteristics. In addition to pH, sorption of metals depends on sorptive concentration, surface coverage, and the type of the sorbent. For oxyanion metals, such as chromate, molybdate and vanadate (Table 1), adsorption on variable charged surfaces is greater at low solution pH than occurs at high pH (i.e., opposite adsorption trend from cations).

One can measure the relative affinity or selectivity of a cation for a sorbent. The properties of the metal cation, sorbent, and the solvent all affect the selectivity. With monovalent alkali metal cations, electrostatic interactions predominate, and the general order of selectivity is $\text{Li}^+ < \text{Na}^+ < \text{K}^+ < \text{Rb}^+ < \text{Cs}^+$ (Xu and Harsh, 1990). This order is related to the size of the hydrated radius. The cation with the smallest hydrated radius, Cs^+ , can approach the surface the closest and be held the most tightly. However, this order is highly variable, depending on the solid surface properties and solution conditions (i.e., pH, ionic strength, and presence of competing or interfering ions).

With divalent metal ions, there is little consistency in the selectivity order. The type of surface and the pH both appear to have major effects on the selectivity sequence. Divalent transition and heavy metal cations, both of which are often sorbed as inner-sphere complexes, are more strongly sorbed than alkali and alkaline earth metals.

Fig. 3 The pH adsorption edges for Pb^{2+} adsorption on montmorillonite at two ionic strengths (I). Metal surface precipitation

As the amount of metal cation sorbed on a surface increases, sorption can proceed from mononuclear adsorption to surface precipitation (Scheidegger et al., 1996). If the formation of a precipitate occurs under solution conditions that would, in the absence of a sorbent, be undersaturated with respect to any known solid phase, this is referred to as surface-induced precipitation. There are several thermodynamic reasons for surface precipitate formation: (1) the solid surface may lower the energy of nucleation by providing sterically similar sites; (2) the activity of the surface precipitate is <1 ; and (3) the solubility of the surface precipitate is lowered because the dielectric constant of the solution near the surface is less than that of the bulk solution. Surface precipitates can arise via polymeric metal complexes (dimers, trimers, etc.) that form on mineral surfaces, and from the sorption of aqueous polymers.

Using in situ molecular-scale analysis (X-ray absorption fine structure spectroscopy (XAFS)) it has been shown that multinuclear metal hydroxide complexes and surface precipitates of Co, Cr, Cu, Ni, Pb, and Zn can form on metal oxides, phyllosilicates, soil clays, and in soils (Fig. 5) (Siebecker et al., 2018; Scheidegger et al., 1996). These metal hydroxide phases occur at metal loadings below a theoretical monolayer coverage and in a pH range well below the pH where the formation of metal hydroxide precipitates would be expected according to the thermodynamic solubility product.

When a surface precipitate consists of chemical species derived from both the aqueous solution and dissolution of the mineral, it is referred to as a coprecipitate. The composition of the coprecipitate varies between that of the original solid and a pure precipitate of the sorbing metal. The ionic radius of the sorbing metal and sorbent ions must be similar for coprecipitates to form. Thus Co, Mn, Ni, and Zn, for example, form coprecipitates on sorbents containing Al and Si, but Pb does not form a coprecipitate because it is considerably larger (ionic radius = 0.12 nm) than Al and Si (0.054 and 0.04 nm, respectively). Coprecipitate formation is most limited by the rate of mineral dissolution that releases Si and Al ions (Scheidegger et al., 1996).

Sorption of Co, Ni, and Zn on phyllosilicates and aluminum oxides can result in the formation of mixed metal-Al hydroxide surface precipitates, which are coprecipitates (Siebecker et al., 2018). The precipitate phase shares structural features common to the hydrotalcite group of minerals and layered double hydroxides (LDH) minerals. The LDH structure comprises stacked sheets of edge-sharing metal octahedra containing divalent and trivalent metal ions separated by anions between the interlayer spaces. Reaction processes controlling Al release from minerals is an important aspect of LDH surface precipitation because the Al slowly diffuses into the octahedral layer of the surface precipitate. For example, the Al^{3+} partially replaces the Ni^{2+} in the octahedral sites of Ni-Al (LDH), which is thermodynamically favored over Ni hydroxide (Scheidegger et al., 1996).

The formation of metal hydroxide surface precipitates is an important sorption process for metal sequestration and immobilization. As the surface precipitates age, metal release is greatly reduced (Scheidegger and Sparks, 1996). Thus, the metals are less prone to leaching into ground and surface waters, and less available for uptake by plants, microbes, and animals.

Fig. 5 Two views (top of (001) plane in panel (A) and side view in panel (B)) of layered double hydroxide mineral surface precipitates (green, blue, and red) on a clay mineral (blue and red). Reproduced from Siebecker MG, Li W and Sparks DL (2018) The important role of layered double hydroxides in soil chemical processes and remediation: What we have learned over the past 20 years. Summary and outlook

Sorption of metals is an important process controlling their transport through the soil and availability to biological organisms. Metals react with soil minerals or soil organic matter through inner-sphere complexation, outer-sphere complexation, and surface precipitation. Continued research to understand sorption processes in soils needs to account for the highly heterogeneous sorbents in soils and how the complexity impacts metal sorption under dynamic conditions. This includes biological influences on sorption reactions (e.g., rhizosphere or biofilm processes) and competing reactions between different sorbent surfaces.

Abstract

Sorption–desorption kinetics have a major impact on the fate of chemicals in soils. Analytical advances enable one to determine better elementary reactions occurring at the molecular level that are part of the overall reaction mechanism, and the extent of multiple sorption processes taking place simultaneously on soil surfaces. Thus, compared to rate parameters previously reported in the literature, those measured with new approaches may be less apparent and more applicable to predict accurately the fate of chemicals in soils using conceptual models.

Key points

- Sorption may result in multiple processes simultaneously occurring on soil component surfaces even after apparent equilibrium is reached in the soil solution.
- The amount of contact time can dramatically affect the extent of desorption
- Probing the chemical forms of adsorbates helps constrain the overall sorption–desorption mechanism.
- Sorption–desorption kinetics are used in mechanistic models to elucidate reaction pathways.
- A predictive model should account for all chemical and transport processes that are involved for a given sorption–desorption mechanism.
- Rate parameters corresponding to chemical kinetics may be employed as input parameters in models to predict chemical fate.
- Chemical kinetics corresponding to elementary reactions may be measured using XAFS combined with PCA and MCR-ALS data-treatment procedures

Introduction

Sorption is a general term that describes the retention of a chemical species by a solid component of a soil. This retention can occur at the liquid–solid interface or within the solid component. The retention mechanism can be adsorption, surface precipitation, or polymerization. Adsorption can refer to an ion exchange mechanism in the diffuse layer as a result of electrostatic forces (nonspecific sorption) or surface complexation between a chemical species and a specific sorption site (specific sorption). Desorption refers to the inverse process, i.e., the release of the chemical species from the surface to the soil solution. Sorption–desorption reactions largely control the fate of chemicals in soils, including plant nutrients, heavy metals, and organic contaminants (Goldberg et al., 2007). These reactions occur in soils over a wide time scale, from milliseconds to days or even years (Sparks, 2003). Since soils are complex and dynamic, a chemical species present in soil solution is likely to be involved in a continuum of multiple reversible and irreversible biogeochemical reactions, including sorption and desorption processes. Among these multiple reactions, those that are irreversible, such as the transformation of sorbed species into secondary phases that remain permanently in a soil, may occur on timescales longer than the longest time period typically studied in the laboratory (i.e. usually less than a year). Those that are reversible hardly reach equilibrium. For example, transport of the soil solution within the soil porous network can specifically affect sorption–desorption reactions as it locally modifies the chemical composition of the soil solution next to sorption sites. This includes the nature and amounts of dissolved species that can potentially compete with sorbed species for sorption sites. Therefore, a reversible sorption or desorption reaction may never reach local equilibrium if it occurs at a time scale longer than the hydraulic residence time of the soil solution (Zhang and Selim, 2011). It is possible that equilibrium is not reached even when the concentration of a dissolved chemical species, experimentally measured in soil solution at different time intervals, does not vary with time. This case can correspond to a steady-state that is out of equilibrium, where the difference between

the total amounts of the chemical appearing in and disappearing from soil solution reaches a constant value (Lasaga, 1998). To quantify these two opposite chemical fluxes occurring in the soil solution at steady-state, including their fractions that correspond to sorption or desorption processes, employing a kinetic approach can be more suitable than a thermodynamic one. Indeed, the former enables one to infer chemical concentration at any time before reaction equilibrium is reached, based on rate parameters that are experimentally determined. The latter enables one to determine chemical activities based on an equilibrium constant that are valid only when true equilibrium is reached. Therefore, the topic of sorption–desorption kinetics is crucial in soil science as it represents a key factor in predicting content and speciation of chemicals present in soils. However, it still represents a field needing additional research, despite the plethora of studies that have been conducted on this topic over recent decades. Most experimental approaches available until now to measure reaction kinetics in soil systems have inherent limitations, which are described in the first part of this chapter. Some emerging kinetic approaches are also discussed in the first part. Typical kinetic behavior of sorption and desorption processes reported in the literature are presented in the second and third parts of this chapter, respectively. It will be demonstrated that the characterization of the solid phases, notably via spectroscopic tools, can help to constrain better the mechanisms involved during sorption or desorption processes. Some models recently developed, where sorption–desorption kinetics were employed to identify the nature of chemical reaction pathways, will be presented in the last part of this chapter. Some of the remaining challenges to apply sorption–desorption kinetics successfully in conceptual models to predict chemical fate in soils accurately will be also discussed in the last part of this chapter.

Experimental approaches to measure kinetics relevant to soil systems

The kinetics of reactions relevant to soil systems, including sorption–desorption reactions, have been studied using various experimental approaches. These approaches could differ from each other by the type of method employed (e.g. batch, stirred-flow, column) or nature of the solid material investigated (i.e. a well-mixed suspension of an individual soil component, or whole soil studied as a mixed suspension or saturated static soil). Details of the apparatuses that have been used to measure kinetics in soil systems can be found elsewhere (Sparks, 1996). This first part of the review mainly focuses on how the rates can depend on the chosen experimental approach employed to measure them. This aspect must be understood to fully comprehend the typical kinetic behaviors of sorption–desorption reactions that have been reported in the literature, which are presented in the next parts of this chapter.

Traditional batch, stirred-flow, and column methods are employed in approaches A, B, C described in Fig. 1, respectively. All transport processes that a chemical species may undergo between the bulk soil solution and a sorption site, specifically when approach A, B, or C is employed, are schematically represented in Fig. 1. Multiple transport processes may occur when a chemical interacts with an individual soil component (Fig. 1, approach A). This includes: (1) transport in the solution phase, which is rapid, and in the laboratory, can be eliminated by rapid mixing; (2) transport across a liquid film at the particle–liquid interface (film diffusion); (3) transport in liquid-filled pores larger than 2 nm; (4) diffusion of a sorbate along pore wall surfaces (surface diffusion); (5) diffusion of sorbate occluded in pores smaller than 2 nm (pore diffusion); and (6) diffusion processes in the bulk of the solid (Sparks, 2003). Soil particles comprise multiple individual soil components that are mixed together as aggregates. In a soil aggregate, transport processes only occur in the region of each individual soil component that is exposed to the soil solution (Fig. 1, approach B). Therefore, an individual soil component inside a soil aggregate may be partially or not at all exposed to the soil solution. In a static saturated soil (e.g. a saturated soil packed in a column, as opposed to a well-mixed soil suspension in a batch or stirred-flow reactor), transport processes can occur between solid particles in the empty spaces of the soil that are parts of the connected pore network (Fig. 1, approach C). Additionally, transport processes can occur inside solid particles of the soil, in regions that are in contact with the connected pore network. Therefore, a soil aggregate inside a static saturated soil may be partially or not at all exposed to the soil solution.

A sorption process leads to the formation of an adsorbate, which is a chemical species retained at the surface of a solid component. The solid surface where sorption–desorption takes place is referred as the adsorbent. The chemical species sorbing to and desorbing from the adsorbent are the adsorptive and desorptive, respectively (Sparks, 2003). The amounts of adsorbate appearing or disappearing at the location where the sorption or desorption process takes place are not determined when a traditional batch, stirred-flow, or column method is employed. Instead, when any of these methods is used, the rates are measured by quantifying the variation in concentration of adsorptive or desorptive in the bulk soil solution. Consequently, the overall rates observed using a batch, stirred-flow, or column method can be apparent. They can include, in addition to the chemical rates (CR) corresponding to the actual sorption or desorption mechanism, those corresponding to all transport processes that occur specifically between sorption sites and the bulk solution when approach A, B, or C is employed (Fig. 1). When multiple processes occur successively or in parallel, the process that has the slowest or fastest rate is considered as the rate-determining step of the overall kinetics, respectively (Lasaga, 1998). Therefore, the kinetics determined using approach A, B, and C described in Fig. 1 may not be representative of the CR if the latter does not represent the rate-determining step of the process observed experimentally. Additionally, none of approaches A, B, and C is ideal to determine how rapidly a given sorption or desorption process, involving a chemical and a specific adsorbent, truly occurs in a saturated soil. With approach A, only the adsorbent being studied is present in the system. Therefore, the possibility that the adsorbent inside a soil aggregate may be only partially or not all available to soil solution, depending on the physical organization of the aggregate, is not considered. Similarly, approaches A and B do not consider that the soil aggregate itself, which contains the specific adsorbent, may be partially or not all available to the solution in the soil,

Fig. 1 Examples of approaches that can be employed to measure kinetics of sorption-desorption reactions relevant to soil systems, and schematic representation of all transport processes occurring in the system when each of these approaches is used. The overall transport occurring in a soil particle (SPT) composed of aggregated individual soil components is equal to the sum of all transport processes occurring in the parts of each individual soil component that are exposed to the soil solution. Similarly, the inner particle transport (IPT) occurring in a static saturated soil is equal to the sum of all transport processes occurring in the parts of each soil particle that are exposed to the soil solution.

Fig. 2 Time-scales of sorption–desorption reactions in soils and various kinetic methods.

depending on the proximity of the aggregate to the connected pore network. In contrast, all transport processes that may affect the overall sorption–desorption kinetics in a static saturated soil can be considered using approach C. However, an adsorptive or desorptive is likely to interfere simultaneously with multiple adsorbents in a soil. Therefore, approaches B and C cannot be employed to determine the kinetics of a sorption–desorption reaction involving a specific adsorbent and occurring in a saturated soil if the rates are measured by quantifying the concentration of the adsorptive or desorptive in the soil solution.

Some techniques, such as P- or T-jump relaxation methods, allow the rates to be determined by varying a physical property of the system, e.g. temperature or pressure. With these techniques, rate constants are determined indirectly as they are measured from linearized rate equations that include parameters determined from equilibrium and modeling studies (Sparks, 2015). The application of an analytical technique, such as batch, stirred-flow, XAFS (X-ray absorption fine structure spectroscopy), and relaxation methods, is limited to a specific time scale (Fig. 2). Batch and stirred-flow techniques do not allow rapid kinetics to be observed as they require at least half a minute to record the first data point.

In contrast, P- and T-jump relaxation techniques can only measure rapid kinetics that are shorter than one minute. The maximum time length covered by XAFS techniques cannot exceed the total allocated beam time, which is typically a few days or less. The minimum time length corresponds to the time required to complete one XAFS scan, which is more than a millisecond and second for Quick and regular XAFS techniques, respectively.

Batch and stirred flow techniques have been so far the most commonly used methods to measure sorption–desorption kinetics in soil systems (approach A or B in Fig. 1, to study a specific soil component or whole soil, respectively). Interpretation of the apparent rates constrained with batch or stirred-flow techniques can be less ambiguous using complementary data, notably the ex-situ characterization of the solid phase, as demonstrated in the next two parts of this chapter. Another powerful approach combines a column, batch, or stirred-flow method with an analytical tool that allows one to determine in-situ the nature and quantity of all main forms of a chemical species, including the forms that are possibly sorbed. For example, Quick X-ray absorption fine structure (Quick-XAFS) spectroscopy was employed with a flow cell (Siebecker et al., 2014) or batch method (Landrot et al., 2010; Vantelon et al., 2019) to follow in-situ the kinetics of rapid environmentally-relevant reactions occurring in soils. This approach allowed one to determine in-situ the speciation of all principal chemical forms of an element, regardless of the fact that these forms were dissolved or sorbed species. For example, Quick-XAFS was employed to measure in-situ the kinetics of nickel that simultaneously adsorbed and precipitated into a layer double hydroxide (LDH) on the surface of a clay, which was mixed with glass beads inside a flow cell (Siebecker et al., 2014). Additionally, XAFS data can be analyzed by a principal component analysis (PCA) followed by a multivariate curve alternative least-square fitting (MCR-ALS) method. This unique data analysis procedure can be done in Fastosh, which is a new XAFS data treatment freeware (Landrot, 2018). This approach allows spectra corresponding to the principal components of an element and the relative quantities of these components to be obtained. This can be notably valuable in identifying reaction intermediates that form during a chemical reaction. For example, PCA & MCR-ALS methods were applied to Quick-XAFS spectra collected at the Fe K-edge during an in-situ experiment where the formation of Fe oxide–organic matter aggregates was followed in a batch reactor under N_2 (Vantelon et al., 2019). This chemometric method provided quantification of the relative amounts (Fig. 3A) and corresponding XAFS spectra (Fig. 3B) of all principal components of Fe that were present throughout the kinetic experiment. These components included an intermediate species that formed temporally during the experiment (Fig. 3A). The results then suggested that the overall mechanism featured two elementary reactions, where the intermediate species was the product and the reactant of the first and second elementary reactions, respectively. Therefore, combining Q-XAFS and the PCA & MCR-ALS procedure is promising as it can potentially single out elementary reactions occurring at the molecular level that are part of the overall reaction mechanism. Measuring rate parameters corresponding to an elementary reaction instead of a group of combined elementary reactions can be beneficial for developing conceptual models that can predict chemical fate in environmental systems, as discussed in the last part of this chapter.

Fig. 3 (A) Relative amount of the three principal chemical forms of iron (Fe) present in a batch reactor and (B) their corresponding pure spectra determined using a PCA & MCR-ALS method applied to XAFS spectra at the Fe K-edge, collected during an in-situ experiment. Shell-by-shell analyses of the pure spectra (not shown), subsequent to their extraction by MCR-ALS, suggested that components A, B, and C corresponded to Fe(II)aqueous, Fe(II) sorbed to humic acids, and Fe–organic matter nano aggregates, respectively. Reproduced with permission from Vantelon D, Davranche M, Marsac R, Fontaine C, Guenet H, Jestin J, Campaore G, Beauvois A, and Briois V (2019) Iron speciation in iron-organic matter nanoaggregates: A kinetic approach coupling Quick-EXAFS and MCR-ALS chemometry. *Environmental Science: Nano*, 6.

Sorption behavior in soils

The kinetics of heavy-metal sorption, determined by a traditional batch or stirred-flow method, on an individual soil component (approach A, Fig. 1) or a soil (approach B, Fig. 1), is typically characterized by a biphasic process in which sorption is initially rapid followed by slow reactions. The rapid step, which occurs over milliseconds to hours, can be ascribed to CR and film diffusion processes. During this rapid reaction process, a large portion of the sorption may occur. For example, a study demonstrated that Ni could sorb rapidly and precipitate into an LDH phase on the surface of the clay in less than 40 min, based on in-situ analyses of the solid–water interface using Quick-XAFS (Siebecker et al., 2014). For Ni sorption on a soil, a study showed that a large portion of total Ni could sorb during the first 24 h and continue to sorb for at least 500 h (Fig. 4). Post-mortem XAFS analyses of the solid phase revealed that Ni was mostly adsorbed onto soil surfaces during the first 24 h. In contrast, it was mostly present as LDH at 650 h (Fig. 4). Similarly, a study demonstrated that molybdenum (Mo) sorption on three different types of soils followed a biphasic behavior. In all three soils, Mo sorption was fastest during the first 8 h, and was mostly associated with the exchangeable fraction. The Mo sorption on each soil continued for 1 year, but at a slower pace than that of the first 8 h. After 1 year, Mo was mostly associated with Fe/Al oxides in two soils. An irreversible sorption site had to be considered to model Mo retention successfully over time in these soils (Sun and Selim, 2019). The biphasic sorption behavior can occur regardless of the affinity of a metal to associate with an absorbent and type of sorption mechanism involved. For example, it was shown that selenate sorption on aluminum hydroxide or goethite was fastest during the first 24 h, although the extent of selenate sorption was significantly higher on aluminum hydroxide than on goethite. Additionally, an inner-sphere and outer-sphere could form on the former and latter absorbent, respectively (Loffredo et al., 2011).

Sorption by metals and oxyanions is characterized by a rapid and reversible stage followed by a much slower non-reversible process or biophasic kinetics. Many investigations have shown that organic contaminants behave similarly. The rapid phase has been ascribed to retention of the organic chemical in a labile form that is easily desorbed. The labile form of the chemical is also available for microbial attack. However, the much slower reaction phase involves the entrapment of the chemical in a nonlabile form that is difficult to desorb and is resistant to biodegradation. This slower sorption–desorption reaction has been ascribed to diffusion of the chemical into micropores of the organic matter and inorganic soil components (Sparks, 2003). The slow diffusion of organic chemicals in soil organic matter (SOM) can be explained by considering SOM as a combination of ‘rubbery’ and ‘glassy’ polymers. The rubbery-like phases are characterized by an expanded, flexible, and highly solvated structure with pores of subnanometer dimensions (holes). Sorption in the rubbery phase results in linear, noncompetitive, and reversible behavior. The glassy phases have pores that are of subnanometer size and sorption in this phase is characterized by nonlinearity and is competitive (Sparks, 2003).

The kinetics of a sorption reaction involving an organic chemical found ubiquitously in the environment is shown as an example in Fig. 5 (Yan et al., 2014). In this study, the adsorptive and adsorbent were an inositol hexakisphosphate (IHP), which represents the most abundant type of organic phosphate (OP) in soils and sediments, and amorphous aluminum hydroxide (AAH), respectively. The [IHP] in solution progressively decreased during the first 6 h and then remained stable after 6 h (Fig. 5A). Between 3 h and 4 days, a fraction of IHP was retained as an inner sphere complex on the surface of AAH, based on the presence of a peak at 6.5 ppm in all solid-state ^{31}P single-pulse magic angle spinning nuclear magnetic resonance spectroscopic (SP/MAS NMR) spectra, which corresponded to AAH reacted with IHP for different time periods (Fig. 5B). Additionally, a fraction of IHP sorbed to AAH progressively transformed, between 6 h and 2 days, into a surface precipitate analogous to aluminum phytate. This was based on attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) analyses of AAH reacted with IHP for different time periods (Fig. 5C). Therefore, sorption of an organic species can result in more than one sorption mechanism, like the example

Fig. 4 (A) Kinetics of Ni sorption onto a soil determined using a batch method (blue dots) and amounts of Ni-LDH and adsorbed Ni measured using post-mortem XAFS analyses of the Ni-reacted soil's solid phase at different time intervals in green and red colors, respectively; (B) linear combination fitting of the EXAFS corresponding to the Ni-reacted soil's solid phase at different time intervals. involving the sorption of an inorganic species shown in Fig. 4. In the case of IHP sorption to AAH, the first sorption mechanism was rapid and occurred within the first 3 h, the second one was slower and started at 6 h although the concentration of IHP in solution did not vary further. This suggested that determining the sorption kinetics by measuring only the concentration of adsorptive in solution can be misleading as sorption processes can continue after the concentration of the adsorptive seems to have reached apparent equilibrium. In both examples shown in Figs. 4 and 5, analyses of the reacted solid phase using spectroscopic tools, i.e. XAFS, ATR-FTIR, and SP/MAS NMR, allowed one to identify more than one sorption process occurring on the surface and to understand the overall sorption behavior better.

Desorption behavior in soils

The amount of contact time between metals and soil sorbents (residence time) can dramatically affect the degree of desorption, depending on the metal and sorbent. This behavior is due to aging mechanisms that can occur when the metal is associated with the sorbent, such as surface precipitation or diffusion into the solid phase. For example, it was mentioned above that the amount of Ni adsorbed in a soil (Fig. 3) or on a clay surface (Siebecker et al., 2014) could progressively precipitate into an LDH phase. This transformation can affect metal desorption kinetics. For example, it was shown that Zn sorption to soils excavated from Brazilian mining areas could result in the formation of Zn insoluble secondary phases, including Zn-LDH, which could lead to a significant decrease in the exchangeable/mobile fraction of Zn in the soils. The desorption kinetics of Zn from the soils where these secondary phases formed was then much slower than from the mine tailings where Zn was mostly present in the exchangeable/mobile fraction (Lopes et al., 2021).

It was demonstrated recently that the retention of antimony (Sb) in soils can increase over time, by a factor of 2–4 between about 2 weeks and 6 months (Verbeeck et al., 2021). Results obtained from XAFS analyses suggested that this increased retention was not due to precipitation as with Ni, but rather micropore diffusion with Sb substitution in surface Fe octahedra of ferrihydrite, and/or changes in surface adsorption geometry (Verbeeck et al., 2021). Another recent study demonstrated that the amount of Pb that could be released from iron oxide decreased with increasing length of aging period, until an aging period of 50 h was reached (Fig. 6A). With an aging period >50 h, the amounts of Pb released were constant. Chemical mapping at the microscopic scale indicated that much more Pb was present inside a Pb-reacted hematite particle aged for 168 h compared to another particle aged for 24 h (Fig. 6B). This suggested that Pb progressively diffused inside the solid particle, which made it less likely to be released to solution (Lu et al., 2020).

It has been demonstrated that as for some metals, with increased residence time the nonlabile portion of the organic chemical in the soil or sediment becomes more resistant to release and is less available for microbial degradation. Soils reacted with desorption agents in the laboratory over a short period of time often show more rapid organic chemical release than field soils that have been contaminated for many years. The difference in release has been ascribed to greater diffusion into micropores of clay minerals and humic components that occurred over longer times in field settings (Sparks, 2003). Some studies, such as Cheng et al. (2019), have reported that the aging effect could also occur over a time period of less than a year. For example, Fig. 7 shows the desorption kinetics of Dechlorane Plus (DP), which is a toxic additive flame retardant and a common soil pollutant, from soils that were aged

Fig. 6 (A) Amounts of Pb released from Pb-reacted iron oxide particles aged for different time periods, using an acid solution at pH 3.0; (B) STEM-EDS mapping and line scan results of elemental distribution (Pb, Fe, and O) on Pb-reacted iron oxide samples aged for various time periods. Blue, red, and green colors refer to Fe, O, and Pb, respectively. Reproduced with permission from Lu Y, Hu S, Liang Z, Zhu M, Wang Z, Wang X, Liang Y, Dang Z, and Shi Z (2020) Incorporation of Pb(II) into hematite during ferrihydrite transformation. *Environmental Science: Nano* 7: 829–841.

for various time periods of 0–260 days. The desorption kinetics systematically followed a biphasic behavior, regardless of the aging effect, as they were rapid during the first 50 h, and then slowly decreased from 50 to 400 h (Fig. 7A). However, the total amount of DP that could be released to solution during these desorption experiments decreased significantly with increasing aging time (Fig. 7A). Results obtained from a new sequential chemical extraction procedure indicated that the amounts corresponding to the labile DP fraction present in the soils decreased with an increasing aging period, while the amounts corresponding to the residual fraction of DP increased with an increasing aging period (Fig. 7B). Therefore, as for some metals in soils, this organic pollutant that adhered to soil components could progressively transform into secondary forms that were more environmentally persistent.

Application of sorption–desorption kinetics to conceptual models

Many studies have used theoretical rate laws to reproduce mathematically the sorption–desorption kinetics measured experimentally. Details of these rate laws are available elsewhere (Selim and Zhang, 2013). Applying rate laws to kinetic data can be potentially useful in achieving two goals. First, it may allow us to identify reaction pathways and infer an overall reaction mechanism involving a chemical present in a soil, thus improving a fundamental understanding of the behavior of a chemical in the soil. Second, it can help to develop conceptual models that can accurately predict the fate of a chemical in environmental systems other than those where the rates have been determined experimentally. Unfortunately, examples of studies where either of these two goals was unambiguously achieved are still rare. In practice, the characterization of an overall reaction mechanism, describing all elementary reactions involved in the reaction, is often not possible when rate laws are applied to kinetic data measured using the methods currently available. The inherent limitations of most kinetic approaches discussed in the first part of this chapter also suggest that the rate parameters derived from rate laws can be apparent, as they may be affected by transport phenomena, and thus cannot be easily implemented in predictive models. These limitations will be described further in the last part of the chapter. This part will also describe some recent conceptual models where sorption–desorption kinetics were characterized to constrain reaction pathways as well as some of the remaining challenges to predicting chemical fate in soil systems successfully, including chemical retention behavior.

Sorption–desorption kinetics may depend on multiple biological, physical, chemical phenomena (Sparks, 2003). Some rate laws are purely empirical as they do not explicitly consider any of these phenomena in their mathematical expression. Consequently, the parameters derived from these rate laws cannot be easily applied to systems other than the ones for which they are determined. This includes the Elovich equation, power function, as well as first or second-order rate laws. Some rate laws can feature some parameters in their mathematical expression that account for chemical or physical aspects of the system. This includes

Fig. 7 (A) Desorption kinetics of Dechlorane Plus (DP) released from soils reacted with DP for specific aging time periods; and (B) labile, stable-adsorbed, and bound-residue fractions determined using a sequential extraction procedure in soils spiked with 0.1, 1, or 10 $\mu\text{g g}^{-1}$ DP. Reproduced with permission from Cheng Y, Ding J, Xie X, Ji X, and Zhang Y (2019) Validation and application of a 3-step sequential extraction method to investigate the fraction transformation of organic pollutants in aging soils: A case study of dechlorane plus. *Environmental Science & Technology* 53: 1325–1333.

chemical nonequilibrium rate laws based on a two-site model, where two reactions are assumed to reproduce the observed biphasic behavior: one fast reaction that quickly reaches equilibrium and a slower one that lasts for a long period of time (Sparks, 2003). Similarly, when a physical nonequilibrium rate law based on a two-site model is used, it is considered that the slow reaction is due to a transport rate-limiting step occurring during the reaction. A stop–flow approach can be employed together with a stirred-flow method to determine whether a process is chemically or physically rate-limited (Sparks, 1996). Alternatively, the energy of activation (E_a), whose value can be measured experimentally by employing the Arrhenius equation, can be used to determine whether a specific elementary reaction, or a set of combined elementary reactions (in this case, E_a is apparent) is chemically or physically rate-limited (Lasaga, 1998). Therefore, the stop flow approach, or E_a , can help determine whether a chemical or physical non-equilibrium rate law should preferentially be used for a specific system. However, the applicability of a given chemical or physical non-equilibrium rate law to multiple soil systems can be limited, as for pure empirical rate laws. Multiple types of sorption sites can be considered in a chemical non-equilibrium rate law. However, the nature of the chemical reactions occurring at these sites is not identified. Physical non-equilibrium rate laws often rely on multiple parameters that are measured empirically in the laboratory (Sparks, 2003).

A theoretical model can be considered mechanistic when it describes all types of retention processes affecting the rates that are observed experimentally. Three mechanistic models, developed over the last decade to reproduce metal sorption–desorption kinetics in soils, are summarized in Table 1. In these models, retention processes could correspond to a specific sorption mechanism such as Ni surface precipitation forming an LDH, or the association between a metal and a major soil sorption pool, e.g. clays, SOM, dissolved organic matter (DOM), which were assumed to reach equilibrium instantaneously. The sorption–desorption rate coefficients corresponding to these processes were inferred by equilibrium partition coefficients, which were calculated using the Windermere Humic Aqueous Model (WHAM) or the Charge Distribution-Multisite Complexation (CD-MUSIC) model. The former can describe the speciation of metals and metalloids associated with soil organic matter (Tipping, 1994). The latter is a surface complexation model that is particularly efficient in predicting metal complexation with some iron oxides (Gustafsson et al., 2011). The kinetics of Ni surface precipitation to LDH was mathematically reproduced using a simple rate law and was not assumed to reach equilibrium rapidly (Shi et al., 2012). However, the rate order of this rate law was empirically set to 0.77 so that the LDH amounts predicted by the model and those determined in-situ by XAFS analyses could match each other. All three kinetic models described in Table 1 could reproduce all retention behaviors well that were measured experimentally using a stirred-flow method. This suggested that the overall retention mechanisms assumed in these models could be valid. However, in a saturated static soil subjected to reactive transport (e.g. a static soil under field conditions, not a mixed soil suspension in the laboratory), the assumption that sorption–desorption processes reach equilibrium may be challenged when these reactions occur at a time scale longer than the hydraulic residence time of the soil solution (Molins and Knabner, 2019).

Some rate constants, corresponding to sorption or desorption processes considered in geochemical models, such as those described in Table 1, were empirically determined by employing a least-squares fitting method. The values of these rate constants were floated freely during the fitting procedure to minimize the difference between the experimental and model results. For example, all rate constants considered in the competitive multi-reaction models employed in Sun and Selim (2019) were empirically determined by a least-square fitting procedure. This was also the case for the rate constants corresponding to all desorption processes considered in the mechanistic models developed in Shi et al. (2012), Shi et al. (2013), and Peng et al. (2018). Therefore, these models, which can help in elucidating retention mechanisms, cannot be employed as purely predictive tools to estimate sorption–desorption kinetics in soil systems. Predictive models should enable these rates to be determined theoretically without the need to measure them in the laboratory, and the model parameters to be scaled based on the experimental data. Moreover, tools that can predict chemical retention behavior in specific regions of a soil cannot be models that consider only the overall geochemistry of the system. They must be essentially reactive transport models that can describe locally the coupled geochemistry, hydrology, biogeochemistry, soil physics, and fluid dynamic processes, which may affect chemical retention behavior simultaneously in different parts of a soil (Steefel et al., 2005). A description and comparison of various reactive transport models currently available can be found in Steefel et al. (2015). Lastly, multiple transport processes within soil particles can occur when a stirred-flow method is employed, even when the soil suspension is well stirred (approach B in Fig. 1). The effects of such

Table 1 Examples of mechanistic models where metal sorption–desorption kinetics were employed to constrain reaction pathways involving various metals.

phenomena on the rates are not considered by the mechanistic models described in Table 1, or other types of models recently applied to reproduce metal sorption–desorption kinetics, such as competitive multi-reaction models (Sun and Selim, 2019). Competitive multi-reaction models consider different sorption sites that a chemical can sorb to. This includes a site at equilibrium where sorption is assumed to occur instantaneously, a site where irreversible sorption occurs, and a site where reversible sorption occurs. A sorbed species associated with the latter site can either reversibly desorb from this site or irreversibly transfer to an additional pool. This pool can represent, for example, the fraction of a sorbed species on a surface that transforms irreversibly into a secondary mineral phase. Therefore, competitive multi-reaction models can potentially reproduce the complex sorption behaviors well that were described in previous parts of this chapter. However, these models may be considered less mechanistic than those described in Table 1 because they do not enable determination of the nature of the chemical reactions occurring at the sorption sites.

Transport kinetics can potentially represent the rate-determining step of a sorption or desorption mechanism and can depend on multiple factors that are specific to a given soil system, including porosity, permeability, tortuosity. In addition, diffusion kinetics can be affected by the electrostatic potential in the diffuse double layer on soil component surfaces, which, in turn, depends on pH, PZC (point of zero charge), and electrolyte concentration (Goldberg, 1992; Tournassat and Steefel, 2021). A well-constrained predictive model should then account for all chemical and transport processes that are involved in a given sorption–desorption process. Chemical kinetics are not dependent on system conditions (e.g. soil physical properties, chemical concentrations, surface loading, pH, or mixing) except for the temperature (Sparks, 2003). Therefore, rate parameters corresponding to chemical kinetics of a specific sorption–desorption mechanism may be used as model input parameters to predict retention behavior in any soil system where this mechanism occurs. This is possible since chemical kinetics essentially correspond to rates of elementary chemical reactions occurring at the molecular scale. The rate parameters corresponding to an elementary reaction can be used in any other process where this reaction is part of the overall reaction mechanism (Lasaga, 1998). In contrast, the rates corresponding to an overall reaction that is essentially a combination of elementary reactions cannot be used in systems other than the one where they are measured. Such an overall reaction can potentially be obtained by combining different types of elementary reactions whose nature may depend on the conditions of the system (Lasaga, 1998). Therefore, a predictive model that could be applied to multiple soil systems, using the same chemical rate parameters, should ideally describe all elementary reactions occurring during a given sorption–desorption process, including those where intermediate species are involved. The model would then constrain the overall kinetics of the process by only predicting transport kinetics, which can depend on the conditions and nature of the soil system. This would still require, however, all soil physicochemical properties that can potentially affect transport to be specified as model input parameters. One of the impediments to developing such an ideal predictive model is the difficulty in quantifying accurately all mass transport processes that occur between the bulk soil solution and sorption sites in a static saturated soil. Old and new approaches to model diffusion processes can be found elsewhere (Molins and Knabner, 2019; Tournassat and Steefel, 2021).

Advances in analytical methods allow for better characterization of mineral distribution in soils and solution transport in porous materials. For example, a method was recently developed to map mineral distribution in rocks in 2-D (Kim et al., 2021). It is based on a machine learning approach where an artificial neural network (ANN) is employed to treat micro X-ray fluorescence (μ XRF) and micro X-ray diffraction (μ XRD) data. Another method, coupling scanning electron microscopy–energy dispersive X-ray spectroscopy (SEM–EDX) with an image segmentation technique, was developed to map mineral distribution in a sandstone rock (Landrot et al., 2012). This method also allowed one to quantify the reactive surface area exposed to the connected pore network of each mineral phase present in the sandstone. In addition, phase-shift tomographic methods, which have emerged over the last two decades, enable one to discriminate better between materials that have similar absorption and refraction properties compared to absorption-based tomographic techniques (Prade et al., 2016). Therefore, these methods can potentially discriminate better between solid, liquid, and gas phases and visualize micro-cracks or pores compared to conventional absorption-based tomographic techniques (Teixidó et al., 2021). Phase-shift tomographic methods particularly benefit from fourth generation synchrotron facilities, which are currently emerging in different parts of the world; these new machines deliver X-ray beams with increased beam coherence and brightness. These methods have been used to observe in-situ the transport of liquid into solid materials containing pores or fractures, such as mortar (Prade et al., 2016), glass, carbon and flax fabrics, as well as a 3-D printed structures (Teixidó et al., 2021). Therefore, these new analytical approaches may be potentially valuable in determining first, the parts of the soil pore network where adsorptives or desorptives are transported in the soil solution and second, the specific regions of solid components that are exposed to the soil solution where sorption–desorption processes occur. Understanding such aspects may represent a prerequisite for developing models that can successfully predict mass transport and chemical retention behaviors.

Conclusions and future directions

The kinetics of some relevant sorption–desorption reactions that occur in soils were presented in this chapter. It was shown that the amount of contact time between some inorganic or organic chemicals and soil sorbents can dramatically affect the extent of desorption of these chemicals, and can progressively transform them into secondary forms that are more environmentally persistent. Sorption of inorganic or organic chemicals in soils may result in multiple processes that occur simultaneously on the surfaces of soil components. Some of these mechanisms can take place even after apparent equilibrium has been reached in the soil solution. Therefore, determining the kinetics of these processes by quantifying only the amounts of adsorptive or desorptive components in solution, using traditional batch or stirred-flow methods, may not allow one to elucidate the full retention behaviors. This chapter has also demonstrated that the use of analytical techniques enabling the characterization of the adsorbates'

chemical forms directly on the soil components where sorption–desorption mechanisms occur, can be crucial to constrain the overall process.

Mechanistic models to study sorption–desorption kinetics is useful for elucidating the main reaction pathways that a given chemical may follow in a soil. In addition, parameters of chemical rates corresponding to a given sorption–desorption process may be employed in conceptual models to predict chemical fate in soil systems where this mechanism occurs. These parameters cannot be determined using any of the experimental approaches described in Fig. 1 because the kinetics measured with these methods may be affected by multiple transport phenomena. Chemical rates must be measured using techniques that can quantify adsorbate concentrations and follow the kinetics of all elementary reactions that are part of a sorption–desorption chemical mechanism, including those involving intermediate species. This may potentially be possible using the emerging approach that combines XAFS with PCA and MCR-ALS data-treatment. Frontiers in the field include the development of theoretical approaches that can quantitatively predict all transport processes that a chemical species may undergo between the bulk soil solution and specific types of sorption sites, including in non-saturated soils.

Abstract

Sorption-desorption hysteresis of anthropogenic organic compounds (AOCs) in soils is essential to the migration, transformation, bioavailability and fate of AOCs in the environment. In this chapter, several topics related to sorption-desorption hysteresis are elaborated, including a definition of hysteresis, distinction between true and artificial hysteresis, quantification methods and possible mechanisms for hysteresis, effects of the properties of soil organic matter (SOM) (i.e., rubbery/glassy states and functional groups), the physiochemical properties of AOCs (i.e., molecular sizes and functional groups) and the environmental factors (i.e., temperature, ionic strength, pH and competitive co-solutes) on hysteresis.

Key points

- Hysteresis is attributed to irreversible pore deformation and sorptive interactions.
- SOM (soil organic matter) with glassy structure can induce significant sorption-desorption hysteresis.
- SOM with rubbery structure or fixed-porous structure cannot induce hysteresis.
- Hysteresis was observed for anthropogenic organic compounds with functional groups and larger molecular sizes.
- Temperature, ionic strength, pH and co-solutes can significantly affect the hysteresis.

Introduction

Nowadays, thousands of tons of anthropogenic organic compounds (AOCs) are produced in factories and used everywhere in our modern life. It is inevitable that some of these AOCs are released into the soil, probably through the uncontrolled disposal of sewage sludge or industrial waste, the applications of pesticides in agriculture, and the atmospheric precipitation of emitted AOCs from the combustion of fuels or biomasses. The contamination of soils by AOCs could cause high risks to the environment and public health. Sorption and desorption of AOCs by soils are the key processes that determine the migration, transformation, bioavailability and fate of AOCs in the environment. Sorption can cause the immobilization of AOCs in soils and generally impede the migration and bioavailability of AOCs in the environment. Desorption, as the reverse process of sorption, could cause the remobilization of sorbed AOCs from soil and enhance the migration and bioavailability of AOCs in the environment (Qiu et al., 2016). Therefore,

Fig. 1 Sorption-desorption isotherm shows (A) reversible hysteresis with closed hysteresis loop and (B) irreversible hysteresis with open hysteresis loop. knowledge of sorption and desorption behaviors of AOCs in soils are essential for assessing the environmental and health risks of released AOCs. Sorption of AOCs by soils can be reversible or irreversible. The ‘reversible’ means that the pathways for sorption and desorption are the same, while the ‘irreversible’ means that their pathways are different. The ‘hysteresis’ in the isotherm (i.e., the desorption branch is higher than the sorption branch) can be used to identify the irreversible sorption. Sorption-desorption hysteresis has been widely observed for AOCs in soils and sediments, which can be categorized into two types (Yang and Xing, 2010a), i.e., reversible hysteresis and irreversible hysteresis. Reversible hysteresis means that complete desorption can be achieved without any intervention (e.g., vigorous solvent extraction), showing a closed hysteresis loop in desorption and sorption branches of an isotherm (Fig. 1A). Irreversible hysteresis means that complete desorption cannot be achieved, showing an open hysteresis loop in the desorption and sorption branches of an isotherm (Fig. 1B) and an extrapolated nonzero sorbed concentration at zero solution-phase concentration.

Soils are mainly composed of minerals and soil organic matter (SOM). The minerals in soils are silicate clays and oxyhydroxide minerals of Si (silicon), Fe (iron), Al (aluminum), Mg (magnesium), Mn (manganese), etc., while the SOM mainly consists of humic substances that have formed by biogeochemical degradation of plant or animal debris and carbonaceous materials such as soot and charcoal (Yang and Xing, 2010b). Generally, sorption of AOCs by soil minerals is several magnitudes lower than that by SOM, and the sorption by soil minerals may become insignificant if soils contain more than 0.1% SOM (Yang and Xing, 2010b). Since the contents of organic matter are within 0.5–3.0% for most soils in the natural environment, the role of soil minerals in sorption-desorption hysteresis of AOCs is expected to be negligible. Therefore, this chapter focuses on the sorption-desorption hysteresis caused by SOM.

Sorption-desorption hysteresis

Sorption-desorption hysteresis may be true or artificial. The sorbed amounts of sorbate after the sorption process are calculated by the mass difference of sorbate in solution before and after sorption (Eq. 1). Desorption experiments are generally conducted by a batch decant-refill method following the sorption experiment, i.e., replacing the aqueous supernatant of sorbate after sorption equilibrium with a sorbate-free aqueous solution, which allows the sorbed-sorbate to desorb into the fresh solution until a new equilibrium is reached. The sorbed amounts of sorbates after the desorption process are calculated by subtracting the amounts of sorbed-sorbate released into the fresh solution from the sorbed amounts at the sorption equilibrium (Eq. 2).

$$q_e = \frac{m_0 - m_e}{M} = \frac{(C_0 - C_e) \times V}{M} \quad (1)$$

$$q'_e = q_e - \frac{m_{Re}}{M} = q_e - \frac{(C'_0 - C'_e) \times V'}{M} \quad (2)$$

where q_e is the sorbed amount of sorbate in sorption process; q'_e is the sorbed amount of sorbate in desorption process; m_0 and m_e are the masses of sorbate before and after sorption, respectively; m_{Re} is the mass of sorbed-sorbate released into the fresh solution; M is the mass of sorbent; C_0 and C_e are the aqueous concentrations of sorbate before and after sorption, respectively; C'_0 and C'_e are the aqueous concentrations of sorbate before and after desorption, respectively; V and V' are the solution volumes in sorption and desorption, respectively. Artificial hysteresis may be caused by the artificial decrease of sorbed amounts in the sorption process (q_e) or by the artificial increase of sorbed amounts in the desorption process (q'_e), which could mainly result from the artificial increase of C_e or the artificial decrease of C'_e . Four main categories of circumstances can be responsible for the artificial change in sorbate concentration (C_e or C'_e) and subsequently the apparent sorption-desorption hysteresis, i.e., (i) the mass loss of

Fig. 2 Schematic diagram of sorption-desorption isotherms with insufficient and sufficient equilibrium times (A) and the example of sorption-desorption isotherms of 1,3,5-trinitrobenzene by a chitin-derived biochar with equilibrium times of 2 days (B) and 15 days (C). Reproduced with permission from Zhu HX, Liu XY, Jiang Y, Zhang M, Lin DH, Yang K (2021) Time-dependent desorption of anilines, phenols, and nitrobenzenes from biochar produced at 700 °C: Insight into desorption hysteresis. *Chemical Engineering Journal* 422: 130584.

sorbent and sorbate from the vials, (ii) the biological degradation of sorbate, (iii) failing to allow the sorption and desorption processes to reach their respective equilibrium, and (iv) the concentration and property change of a third phase (e.g., colloids) after the dilution in desorption process.

The mass loss of sorbent and sorbate from vials can be avoided by careful management of the experiments and proper selection of vials. The biological degradation of sorbate can be addressed by adding biocides. However, nonequilibrium sorption and desorption can be the most serious circumstance for artificial hysteresis. It is commonly acknowledged that contact time of weeks or months are required for approaching the true sorption and desorption equilibrium in the AOC-soil system (Huang et al., 1998). Hence, short contact time such as several hours to several days for sorbate and sorbent could be responsible for this type of artificial hysteresis. In this circumstance, the sorption process of sorbate continues during the desorption experiment, resulting in the underestimating of q_e , while the desorption process of sorbate is stopped before the true equilibrium, leading to the overestimating of q_e' . Accordingly, an unrealistically larger difference between the apparent q_e and q_e' is observed, i.e., the artificial hysteresis (Fig. 2A). For example, significant hysteresis was observed for the sorption-desorption of 1,3,5-trinitrobenzene by a chitin-derived biochar with a contact time of 2 days (Fig. 2B), while much less hysteresis was observed with a longer contact time (Fig. 2C) (Zhu et al., 2021). The failure to allow the sorption and desorption of 1,3,5-trinitrobenzene by the biochar to reach the true equilibrium within 2 days could be responsible for the artificial hysteresis. Usually, nonequilibrium desorption contributes more than nonequilibrium sorption to this type of artificial hysteresis, because the desorption process is frequently slower than the corresponding sorption process due to the slower diffusion process in desorption.

The fourth category of circumstance for artificial hysteresis may occur when there is an 'invisible' partition phase (e.g., dissolved organic matter or macromolecule) for AOCs that coexisted in the sorption system. The partition phase could significantly enhance the apparent solubility of AOCs in aqueous solution and thus lower their q_e values to soils. The refilling solution used in the following desorption process is generally free of both the sorbate and the organic matter/macromolecule. The decrease in the partition phase of the desorption process can generate a higher q_e' value. Hence, an unrealistically larger difference between the apparent q_e and q_e' for AOCs to soils is observed, i.e., the artificial hysteresis.

Hysteresis indices

Although the sorption-desorption hysteresis could be artificial, true hysteresis for the sorption and desorption of organic compounds by soils is commonly observed where the separation of the sorption and desorption isotherms of organic compounds by soils is not attributed to the experimental artifacts. Quantification of the extent of sorption-desorption hysteresis is of great importance for evaluating the sorption and desorption behaviors of organic compounds in soils and further for assessing their potential environmental and health risks. Several empirical hysteresis indices (HIs) have been used to quantify the sorption-desorption hysteresis (Huang et al., 1998; Sander et al., 2005), which have a similar form representing the relative difference between the characteristics of sorption and desorption isotherms (Eq. 3).

$$HI = \frac{|W_{\text{sorb}} - W_{\text{desorb}}|}{W_{\text{sorb}}} \quad (3)$$

where W could be one of the following: sorbed amount of sorbate (q_e), distribution coefficient ($K_d = q_e/C_e$), the slope of isotherm (S), the area under isotherm (A) and the exponent of Freundlich equation fitted to the isotherm (N); W_{sorb} and W_{desorb} are those parameters in the sorption and desorption isotherms, respectively. Hysteresis usually occurs for the nonlinear sorption and desorption of organic compounds by soils, where the values of parameters q_e , K_d and S vary with the aqueous concentrations of organic compounds. Hence, the sorbate concentration should be fixed when comparing or discussing the HI based on the parameters above. Conversely, the HI based on parameters A and N are independent of sorbate concentration, because the values of

A and N do not vary for the nonlinear isotherms. It is not necessary to fix the sorbate concentration when analyzing the HI based on A or N . Although the empirical HIs mentioned above are convenient for identifying the extent of sorption-desorption hysteresis of organic compounds by soils, one major drawback of them is that they depend arbitrarily on the dilution ratio in the desorption process. For true sorption-desorption hysteresis, a higher dilution ratio could decrease the value of C_0' and increase the value of q_e' in Eq. (2), and subsequently lead to a greater hysteresis. Thus, the dilution ratio should be fixed when comparing HIs for different sorption-desorption of AOCs by soils. The greater hysteresis could be identified by the larger HI value when the dilution ratio remains constant.

Possible mechanisms of sorption-desorption hysteresis

Sorption-desorption hysteresis (i.e., irreversible sorption) of AOCs by soils could be caused by the irreversible pore-filling and pore-emptying. The possible mechanisms of true hysteresis include the irreversible pore deformation of soils during the sorption-desorption processes (Sander and Pignatello, 2005; Braida et al., 2003) and the irreversible sorptive interaction (i.e., chemical bonds) between AOCs and soils (Hameed et al., 2020). There are two main categories of irreversible pore deformation that are responsible for sorption-desorption hysteresis, i.e., pore dilation (or pore creation) and formation of closed interstitial space. First, the pore volume of sorbent material with flexible structure (e.g., glassy polymer) is postulated to increase as a result of pore creation or dilation caused by the sorption of organic molecules. However, the created or dilated pores do not relax freely when the fresh solution is added during the desorption of organic molecules (Sander and Pignatello, 2005). As the pore volume of the sorbent is larger in the desorption process than that in the sorption process, the pathways for sorption and desorption of organic compounds are different, resulting in the irreversible sorption and desorption (Fig. 3).

Second, pore deformation of the sorbent during the sorption-desorption process is likely to induce the formation of closed interstitial space, where the sorbed molecules could no longer exchange freely with molecules in the aqueous phase (Braida et al., 2003). Some pores of the sorbent may be swollen and open as a result of the sorption of organic molecules at relatively high concentrations, and then collapse when the external concentration decreases abruptly with the addition of fresh solution in the desorption process. The sorbed organic molecules in the collapsed pores are likely to become entrapped and unable to re-equilibrate with the organic molecules at a decreased concentration in the aqueous phase (Fig. 4). The mechanism of irreversible pore deformation has been successfully used to explain the sorption-desorption hysteresis of organic compounds by soils or the components of soils, such as naphthalene and 1,4-dichlorobenzene by kerogenous organic matter, 1,3-dichlorobenzene and 1,2,4-trichlorobenzene by humic acids and a peat soil (Sander and Pignatello, 2005; Sander et al., 2005).

The sorption and desorption behaviors of AOCs by soils is largely determined by the sorptive interactions (e.g., Van de Waals forces, π - π interactions, hydrogen bonds and chemical bonds), in addition to the pore structure of soils mentioned above. The AOCs sorbed by soils through physical interactions (e.g., Van de Waals forces, π - π interactions and hydrogen bonds) are easily desorbed with the addition of fresh solution in the desorption process, due to the relatively lower energy of those physical interactions. However, the desorption process of AOCs sorbed through chemical interactions (e.g., covalent bonds) is more difficult because of the much higher energy of chemical interactions. Chemical interactions (e.g., covalent bonds) have been identified in the sorption

Fig. 3 Schematic diagram of matrix expansion of soil organic matter (SOM) by the sorption of anthropogenic organic compounds (AOCs) that are responsible for sorption-desorption hysteresis.

Fig. 4 Schematic diagram of the formation of closed interstitial space and entrapment of anthropogenic organic compounds (AOCs) in soil organic matter (SOM) that is responsible for sorption-desorption hysteresis.

Fig. 5 Schematic diagram of irreversible sorptive interactions (i.e., covalent bonds) between anthropogenic organic compounds (AOCs) and soil organic matter (SOM) responsible for sorption-desorption hysteresis.

of aromatic amines, phenols, pesticides, explosive compounds, and polycyclic aromatic hydrocarbons by soils or the components of soils (Thorn et al., 1996; Thorn and Kennedy, 2002; Hameed et al., 2020). The irreversible sorption interactions could be another possible mechanism that is responsible for the sorption-desorption hysteresis of AOCs by soils (Fig. 5).

Effects of properties of SOM on sorption-desorption hysteresis

Although minerals and SOM are the two main components of soils, SOM is dominantly responsible for the sorption and desorption behaviors of organic compounds in soils. Soil organic matter consists mainly of humic substances (e.g., fulvic acids, humic acids and humins) and carbonaceous materials (e.g., black carbon). Humic substances are complex and heterogeneous mixtures of polydispersed materials formed by biochemical and chemical reactions during the decay and transformation of plant and microbial remains (a process called humification). Black carbon is formed either by carbonization (charring) of organic matter during combustion (charcoal particles) or by condensation from the gaseous phase in reducing flames (soot particles). Both humic substances and black carbons are important geo-sorbents for organic compounds. The effects of their properties on the sorption-desorption hysteresis of organic compounds will be elaborated below.

Humic substances

Rubbery and glassy domains of humic substances

Humic substances are macromolecular organic solids, which are suggested to comprise two principal reactive domains: a highly amorphous, 'soft' or 'rubbery' domain and a condensed, 'hard' or 'glassy' domain (Sander et al., 2006). Generally, the two different domains exhibit distinctly different sorption behaviors for AOCs. For example, sorption of AOCs by the rubbery domain appears to be linear, fast and noncompetitive, whereas sorption by the glassy domain appears to be nonlinear, slow and competitive. Sorption of AOCs by the rubbery domain is a bulk process (i.e., partition), similar to the dissolving of AOCs in organic solvents, while sorption by the glassy domain is a surface process (i.e., adsorption) in which the AOCs adhere to the surface of an adsorbent (Sander et al., 2006). Moreover, it was observed that the two different domains exhibit distinctly different sorption-desorption hysteresis for organic compounds. For example, there was no sorption-desorption hysteresis for phenanthrene by a topsoil (Chelsea II) with a mainly rubbery domain, whereas significant sorption-desorption hysteresis was observed for phenanthrene by the subsurface sandy soil (Wagner II) with a mainly glassy domain (Weber Jr et al., 1998). Weber et al. suggested that the sorption-desorption hysteresis was attributed to the irreversible entrapment and/or slow desorption rate of sorbed molecules within porous structures of the glassy domain. The larger glassy domain a soil contains, the greater extent of sorption-desorption hysteresis it exhibits (Weber Jr et al., 1998).

Sander et al. conducted a series of studies to further investigate the mechanisms of sorption-desorption hysteresis of AOCs by a glassy organic matter (Sander and Pignatello, 2005; Sander et al., 2006). They observed that sorption and desorption of naphthalene by the glassy organic matter were reversible at low solute concentration, but were irreversible at high solute concentration. The glassy organic matter could be referred to as a particle that consists of many macromolecules with a microporous network (Sander and Pignatello, 2005). It was proposed that naphthalene at low concentration merely filled the existing voids of glassy organic matter without inducing significant deformation. However, naphthalene at high concentration could dilate the existing voids of glassy organic matter or create new voids, resulting in the significant swelling of organic matter. Matrix relaxation of the glassy organic matter was incomplete, therefore, the structure of organic matter after the sorption-desorption cycle was different from the original one, i.e., the deformation of glassy organic matter is irreversible (Sander and Pignatello, 2005). The swollen organic matter could provide more sorption sites for AOCs and induce higher sorbed amounts in desorption cycle than that in sorption cycle.

Fig. 6 Proposed mechanism for naphthalene (NAPH) sorption and desorption by a glassy organic matter. Reproduced with permission from Sander M, Pignatello JJ (2005) An isotope exchange technique to assess mechanisms of sorption hysteresis applied to naphthalene in kerogenous (glassy) organic matter. *Environmental Science & Technology* 39: 7476–7484.

Therefore, it was proposed that the sorption-desorption hysteresis of naphthalene at high concentration was attributed to the irreversible deformation of glassy organic matter (Fig. 6).

The enhanced sorption of a solute by a sorbent pre-exposed to the same solute or a similar solute with high concentrations is similar to the 'condition effect' (i.e., enhanced repeat sorption) of glassy polymers, which supports a pore deformation mechanism for the sorption-desorption hysteresis of a solute by glassy polymers (Sander et al., 2006). Additionally, the sorption-desorption of AOCs by rubbery organic matter and rubbery polymers are both reversible. Thus, it is possible to hypothesize that the sorption-desorption behaviors of organic compounds by humic substances are similar to those by polymers. Rubbery and glassy are the two main states of macromolecule polymers, which could be interconverted at a glassy transition temperature (T_g). The rubbery state ($T > T_g$) could be regarded as the segmental flexibility of the macromolecules, with the structure being readily recovered after exposure to an applied external condition such as sorption. With $T < T_g$, the segments of macromolecules become inflexible (i.e., glassy state), with the structure being slowly rearranged and not recoverable after sorption. Hence, excess free voids for sorption were created. Sorption and desorption in the rubbery state of macromolecules is reversible because the structure is readily recoverable during the sorption-desorption cycle. However, the sorbed amounts in the glassy state of macromolecules during the desorption cycle are larger than that during the sorption cycle, due to the increase in free voids of macromolecules after irreversible deformation for sorption. Since the rubbery and glassy states of macromolecules can be interconverted by changing temperature, the sorption-desorption hysteresis can be changed simultaneously. Conditioning-annealing studies using chlorobenzene as a conditioning agent and polychlorinated benzenes as test compounds in a second sorption step have been conducted to further confirm the above hypothesis (Sander et al., 2006). The conditioning effects and sorption-desorption hysteresis were observed for a peat soil, a soil humic acid, and poly-vinyl chloride (a model glassy polymer), but not for poly-ethylene (a model rubbery polymer). The conditioning effects and sorption-desorption hysteresis for the peat soil and the humic acid disappeared after annealing between 45 °C and 91 °C. However, at environmentally relevant temperatures, it is expected that the conditioning effects could not completely relax and the sorption-desorption hysteresis would not disappear.

Plasticization of humic substances

It was observed that the concentration-dependent sorption-desorption hysteresis of 1,4-dichlorobenzene and naphthalene by a Beulah-Zap lignite was similar, i.e., the hysteresis index increased with the increase in solute concentration. However, the concentration-dependent sorption-desorption hysteresis of 1,4-dichlorobenzene by a Pahokee peat soil was reverse, i.e., the hysteresis index decreased with the increase in solute concentration (Sander and Pignatello, 2009). Clearly, it is the properties of sorbents that are responsible for the differences in concentration-dependent hysteresis. This can be explained by the influence of plasticization in addition to the matrix flexibility of sorbents. Semi-permanent holes in sorbents are affected not only by temperature but also by solute concentration. With increasing sorbate concentration, the sorbate-polymer interactions become dominant over the polymer-polymer interactions, leading to an increase in polymer segmental flexibility and a reduction in the glassy transition temperature. This is regarded as the plasticization (Sander et al., 2006). The transition of glass to rubbery state is induced at the isothermal glass transition concentration (S_g) of the sorbate. Sorption-desorption hysteresis of AOCs by glassy sorbents is significant due to irreversible matrix deformation of the sorbent, whereas hysteresis by both the rubbery sorbent (highly

Fig. 7 Schematic diagram of hysteresis as a function of matrix stiffness. The arrows point in the direction of increasing plasticization of Pahokee peat (PP) or Beulah-Zap lignite (BZL) with the loading of a sorbate. Reproduced with permission from Sander M, Pignatello JJ (2009) Sorption irreversibility of 1,4-dichlorobenzene in two natural organic matter-rich geosorbents. *Environmental Toxicology Chemistry* 28: 447–457.

flexible) and completely fixed-pore sorbents (inflexible) are negligible. Sander and Pignatello proposed that there should be an apex of sorption-desorption hysteresis of sorbate with the increase in matrix stiffness of sorbents from rubbery sorbents to completely fixed-pore sorbents (Sander and Pignatello, 2009). Hysteresis increases with the increase in matrix stiffness of sorbents from zero (for rubbery sorbents) to the apex, and then decreases with the increase in matrix stiffness of sorbents from the apex back to zero (for completely fixed-pore sorbents) (Fig. 7). The change in hysteresis corresponds to the matrix stiffness of glassy sorbents. For a glassy sorbent with matrix stiffness below the value that corresponds to the apex of hysteresis (i.e., the rubbery side of the apex), hysteresis would decrease with the increase in degree of plasticization, i.e., the increase in sorbate concentrations. By contrast, for a glassy solid with matrix stiffness above the value that corresponds to the apex of hysteresis (i.e., the fixed-pore side of apex), hysteresis would increase with the increase in degree of plasticization. The T_g of Pahokee peat and Beulah-Zap lignite are 52 °C and 115 °C, respectively, where the Pahokee peat was suggested to lie on the rubbery side of the apex and the Beulah-Zap lignite on the fixed-pore side of it. The 4-dichlorobenzene at low concentration was favorably sorbed in the holes of relatively rigid domains of Pahokee peat where it dilated the existing holes or created new holes, but this was not enough to substantially soften the Pahokee peat. Thus, sorption-desorption hysteresis was observed. However, with increasing 1,4-dichlorobenzene concentration, the plasticization of Pahokee peat became more significant, leading to enhanced reversibility of hole expansion and creation and subsequently the weaker sorption-desorption hysteresis of 4-dichlorobenzene at relatively high concentration than that at relatively low concentration.

Functional groups of humic substances

Sorption and desorption behaviors of AOCs by humic substances are determined not only by the structure of humic substances mentioned above, but also by the interactions between AOCs and humic substances, including both physical and chemical interactions. Physical interactions between organic compounds and humic substances, e.g., hydrophobic interaction, π - π interaction and hydrogen-bonding interaction, are common with relatively low sorption energy and are reversible during the sorption-desorption cycle. For example, sorption and desorption of naphthalene, nitrobenzene, 4-methylnitrobenzene, 2,4-dichlorophenol, 4-nitrophenol by a humus-like substance humified from lignin were all observed to be reversible in our previous study, because the sorptive interactions of the humus-like substance for naphthalene, nitrobenzene, 4-methylnitrobenzene (i.e., hydrophobic interaction and π - π interaction) and for 2,4-dichlorophenol, 4-nitrophenol (i.e., hydrophobic interaction, π - π interaction and hydrogen-bonding interactions) are reversible (Ren et al., 2019). Chemical interactions between AOCs and humic substances such as covalent bonds are common with much higher sorption energy and are irreversible during the sorption-desorption cycle. Amino groups of aromatic amines could interact with certain carbonyl or carboxyl groups of humic substances to form covalent bonds (i.e., imines or amides, Fig. 5), generating unextractable residue and significant sorption-desorption hysteresis. For example, Thorn et al. observed the irreversible combination (i.e., imine bond) of aniline with humic and fulvic acids through the characterization of ^{15}N nuclear magnetic resonance (NMR) spectra (Thorn et al., 1996). Thorn et al. also observed the covalent binding of five reduced TNT amines to soil humic acids through the ^{15}N NMR investigation (Thorn and Kennedy, 2002). Coupling reaction is another kind of chemical interactions between AOCs and humic substances that also could generate unextractable residue and sorption-desorption hysteresis. For example, oxidative couplings of fungicide cyprodinil and herbicide 2,4-dichlorophenoxyacetic acid with humic acids were observed through NMR characterization. Other examples include explosive compounds and phenols.

Black carbon

Structures of black carbon

Black carbon is recognized as pyrogenic carbonaceous matter (e.g., combustion soot, charcoal and biochar) that is produced by natural processes (e.g., natural vegetation fires) or anthropogenic processes (e.g., anthropogenic combustion of fossil fuels, wood

Fig. 8 Dynamic molecular structure of plant biomass-derived black carbon (biochar) across a charring gradient and schematic representation of the five proposed char categories and their individual phases. and other biomass) and subsequently discharged into the environment. Charcoal and biochar are usually produced by pyrolyzing plant biomass at temperatures typically between 100 °C and 700 °C under limited-oxygen conditions. The chemical composition and structural properties of biochar are determined mainly by the pyrolysis temperature and physiochemical properties of the biomass precursors. After detailed characterization (e.g., surface area, XRD, NEXAFS, and FTIR) of wood- and grass-derived biochars prepared with pyrolysis temperatures from 100 °C to 700 °C, Keiluweit et al. suggested that there are five distinct categories of biochar (Keiluweit et al., 2010): (i) *unaltered plant materials*: at the initial stage of charring (100–200 °C), loss of water and initial dehydration reactions of plant precursors occur and the native structure of the plant biopolymers (e.g., cellulose, hemicellulose, and lignin) are preserved; (ii) *transition char*: plant precursors increasingly undergo dehydration and depolymerization of biopolymers at this charring stage (200–350 °C), creating volatile dissociation products with small molecular weight, but the cellulose retains notable portions of its crystallinity; (iii) *amorphous char*: cellulose is almost completely depolymerized; condensation reactions occur at this charring stage (350–500 °C), forming small aromatic units arranged in random order and some oxygen-containing intermediates; the aliphatic components are ‘fixed’ in the aromatic matrices resisting volatilization and degradation, suggesting a disintegrated and randomly disordered C phase; (iv) *composite char*: turbostratic crystallites are formed at this charring stage (500–700 °C); aromatic, aliphatic, and O-containing components are preserved, forming the amorphous matrix surrounding turbostratic crystallites, i.e., turbostratic crystallites embedded in a low-density amorphous phase; (v) *turbostratic char*: at temperatures higher than 700 °C, the nanoporous phase of turbostratic crystallites with increasing long-range order are formed (Fig. 8).

Pyrolysis temperatures of black carbon

The black carbon in soils and sediments is regarded as an effective sorbent for AOCs due to its large surface area and high reactivity. The sorption and desorption behaviors of AOCs by biochars with different chemical compositions and structural properties are quite different. According to the characteristics (e.g., aromaticity, aliphaticity and porosity) of biochars mentioned above, those produced at low pyrolysis temperatures (i.e., the unaltered plant materials) could be regarded as a rubbery solid; those produced at moderate pyrolysis temperatures (i.e., the transition char and amorphous char) could be regarded as a glassy solid; whereas those from pyrolysis at high temperatures (i.e., the composite char and turbostratic char) could be regarded as fixed-pore solids. According to the significant sorption-desorption hysteresis of organic compounds by glassy SOM and the insignificant hysteresis by rubbery SOM and SOM with fixed-pore structure as discussed in Section “The plasticization of humic substances”, sorption of AOCs is likely to be reversible for biochars from low and high pyrolysis temperatures, but potentially irreversible for biochars from moderate pyrolysis temperatures. Ren et al. observed that sorption of nitrobenzene, 4-methylnitrobenzene, 4-nitroaniline, 2,4-dichlorophenol, 4-nitrophenol and naphthalene by a lignin material treated at 200 °C were all reversible (Ren et al., 2019). The sorption mechanism of AOCs by biochars with low pyrolysis temperature is by partitioning, whereby the biochars can be regarded as partition media with rubbery structure. Sorption of AOC by rubbery solids is commonly reversible. Zhu et al. reported that sorption of aniline, 4-nitroaniline, phenol, 4-nitrophenol by a wood-derived biochar pyrolyzed at 700 °C were all reversible, and sorption of nitrobenzene by five biochars (i.e., wood-, chitin-, cellulose-, lignin- and rice straw-derived biochars) that pyrolyzed at 700 °C were also reversible (Zhu et al., 2021). Braidia et al. investigated the sorption hysteresis of benzene by a wood-derived

charcoal produced at 400 °C and attributed the hysteresis to the glassy structure of charcoal and the pore deformation of charcoal by sorption of benzene (Braida et al., 2003). The swelling of charcoal by benzene was confirmed by liquid displacement and sedimentation measurements. Three scenarios of pore deformation were proposed as being responsible for the sorption-desorption hysteresis of benzene by charcoal, i.e., (i) leakage of sorbate into closed sectors where it is no longer in contact with solute in bulk solution; (ii) irreversible pore expansion; and (iii) contraction of pores and trapping of sorbate within the collapsed structure. The biochars with moderate pyrolysis temperature should have a glassy rather than the rigid, fixed-pore structure. Wang et al. also observed the sorption-desorption hysteresis of AOCs (i.e., nitrobenzene, naphthalene, atrazine) by a rice straw-derived biochar with moderate pyrolysis temperature (400 °C), where the hysteresis and the desorption were weakened when the leachable pyrogenic organic carbon was removed from the biochar by alkaline solution (Wang et al., 2017). The leachable and non-leachable pyrogenic organic carbons could be regarded as the sources of glassy and fixed porous structures of biochar, respectively. The removal of leachable pyrogenic organic carbon changed biochar from a glassy to a fixed-pore solid, reducing the sorption-desorption hysteresis of AOCs.

Therefore, it could be concluded that (i) sorption and desorption of organic compounds by biochars with low pyrolysis temperatures (100–300 °C) should usually be reversible, mainly due to the rubbery structure of biochars and the reversible partition mechanism; (ii) sorption and desorption of organic compounds by biochars with moderate pyrolysis temperatures (300–500 °C) could be irreversible due to the glassy structure of biochars and the irreversible pore deformation mechanism or the irreversible interactions; (iii) sorption and desorption of organic compounds by biochars with high pyrolysis temperatures (500–700 °C) should usually be reversible due to the fixed-nanoporous structure of biochars.

Functional groups of black carbon

With increasing pyrolysis temperature, the amount of oxygen-containing functional groups of black carbon would normally decrease, in addition to the structure change. Irreversible interactions (e.g., covalent bonds) are possibly formed between the functional groups of black carbon and AOCs, and could subsequently be responsible for the sorption-desorption hysteresis. For example, significant sorption-desorption hysteresis of oxytetracycline was observed for rice straw-derived biochars pyrolyzed at 300 °C, 400 °C and 500 °C, but not for biochars pyrolyzed at 200 °C, 600 °C and 700 °C (Fig. 9) (Hameed et al., 2020). The biochars with moderate pyrolysis temperatures (300–500 °C) commonly have plenty of residue carboxyl groups (—COOH) which could form amide bonds with the amino groups (—NH₂) of oxytetracycline. Although biochars with low pyrolysis temperatures (100–200 °C) also contain abundant carboxyl groups from the plant precursors, sorption of AOCs to biochars is dominated by the partition mechanism, where irreversible chemical interactions are probably not essential and the sorption of oxytetracycline is reversible. Biochars, however, with high pyrolysis temperatures (500–700 °C) usually have far fewer carboxyl groups because of decomposition reactions and probably could not interact with oxytetracycline through the irreversible chemical bonds.

Effects of physiochemical properties of anthropogenic organic compounds on sorption-desorption hysteresis

Molecular sizes of anthropogenic organic compounds

For humic substances and low temperature-pyrolyzed black carbon with rubbery structure, sorption and desorption of AOCs are mainly dominated by the reversible partition mechanism. Generally, sorption-desorption hysteresis is absent no matter what the difference is in molecule sizes of AOCs. For example, sorption of nitrobenzene, 4-methylnitrobenzene, 4-nitroaniline, 2,4-dichlorophenol, 4-nitrophenol and naphthalene, which have different molecular sizes, by a lignin-derived humus-like substance were all reversible. However, for humic substances and moderate-temperature pyrolyzed black carbon with glassy structure or high temperature-pyrolyzed black carbon with fixed-porous structure, sorption and desorption of AOCs are mainly dominated by pore-filling and pore-emptying mechanisms; there is a steric hindrance effect and the role of molecular size is important. Normally, the rates of sorption and desorption of AOCs should depend on their diffusion rate through the pores of glassy or fixed-porous solids, which is negatively correlated with the molecular sizes of the AOCs. Therefore, sorption and desorption rates of AOCs with larger molecular sizes are likely to be slower. The slow rate of sorption-desorption could be an important cause of artificial sorption-desorption hysteresis. The AOC with larger molecular size and slower rate of sorption or desorption by glassy and fixed-porous SOM is prone to be associated with apparent and artificial sorption-desorption hysteresis. For example, it was reported that the sorption of aniline, 4-nitroaniline, phenol, 4-nitrophenol by a wood-derived biochar pyrolyzed at 700 °C was all reversible within 2 days. Sorption of nitrobenzene by five biochars (i.e., wood-, chitin-, cellulose-, lignin- and rice straw-derived) pyrolyzed at 700 °C was also reversible within 2 days. However, significant sorption-desorption hysteresis was observed for 1,3,5-trinitrobenzene with a relatively larger molecular size by the five biochars. It was confirmed that 2 days were required for the sorption or desorption equilibrium of aniline, 4-nitroaniline, phenol, 4-nitrophenol and nitrobenzene by the biochars, while 5 days and 15 days were needed for the equilibrium of 1,3,5-trinitrobenzene by the wood-derived and the chitin-derived biochars, respectively, and more than 30 days for the other three biochars (Zhu et al., 2021).

Apart from the slow sorption and desorption rates, AOCs with larger molecular sizes were considered to induce irreversible pore deformation of SOM to a greater extent or to combine with SOM through stronger interactions, resulting in a more significant sorption-desorption hysteresis. Zhao et al. observed that sorption-desorption hysteresis of perfluorocarboxylates by sediments increased with the increase in molecular chain length (e.g., C6, C8, C9 and C10), and proposed that the perfluorocarboxylates with longer chain length could form stronger interactions with sediments and could also cause irreversible structural rearrangement of the sediment and entrapment of molecules in the sediment (Zhao et al., 2012). Bhandari and Xu observed that sorption-desorption hysteresis of phenolic compounds by two surface soils increased with the increase in molecular size, e.g., phenol < cresol < naphthol (Bhandari and Xu, 2001). Ding and Rice observed that sorption-desorption hysteresis of phenanthrene was more significant than that of naphthalene by two natural organic matters (Ding and Rice, 2011). Higher sorption affinity for SOM and AOC with larger molecular size was probably responsible for the more significant hysteresis.

Functional groups of anthropogenic organic compounds

The functional group of AOCs is another important factor that determines the sorption-desorption hysteresis by soils. AOCs containing functional groups that can form irreversible interactions (e.g., covalent bonds) with soils could induce the hysteresis. For example, significant sorption-desorption hysteresis was observed for oxytetracycline by rice straw-derived biochars with moderate pyrolysis temperatures (e.g., 300–500 °C) due to the formation of amide bonds between the amino group ($-\text{NH}_2$) of oxytetracycline and the carboxyl groups ($-\text{COOH}$) of biochars. However, no hysteresis was observed for phenanthrene due to the lack of a polar functional group (Hameed et al., 2020). Similarly, the observed imine bonds of aniline reacted with soil humic and fulvic acids and five reduced TNT amines with soil humic acids could also induce sorption-desorption hysteresis, due to the irreversible combination of amino groups of amines and carbonyl or carboxyl groups of humic substances. Fungicide cyprodinil and herbicide 2,4-dichlorophenoxyacetic acid with polar functional groups could react with humic substances through oxidative couplings, which is also a type of irreversible combination and could cause significant sorption-desorption hysteresis. Zhao et al. observed that the sorption-desorption hysteresis of perfluoroalkane sulfonates by sediments was more significant than that of perfluorocarboxylates with the same chain length, and proposed that the sulfonate group of perfluoroalkane sulfonates could strongly interact with the sediment and be responsible for the hysteresis (Zhao et al., 2012).

Effects of environmental factors on sorption-desorption hysteresis

Temperature

The sorption-desorption hysteresis of AOCs by soils could be influenced by temperature from two aspects, i.e., changing the rate of sorption or desorption and the structure of SOM. Higher temperatures could accelerate the movement of molecules and was confirmed to increase the rates of sorption and desorption of AOCs by soils, which consequently could shorten the time required to reach the sorption-desorption equilibrium and reduce artificial hysteresis. Generally, sorption through physical interactions is an exothermic process, while the corresponding desorption is endothermic. In addition to increased rates of sorption and desorption, higher temperatures could enhance the amounts of AOCs desorbed by soils, but reduce those sorbed, changing the sorption-

desorption equilibrium to be desorption-favorable. For example, Carroll et al. observed that desorption of polychlorinated biphenyls from soils and sediments was significantly enhanced by increasing temperature (Carroll et al., 1994). Thermal desorption technology (i.e., treating the organic contaminated-soils at high temperatures) has widely been used for removing organic contaminants in soil remediation. However, the enhancement of desorption and the reduction in sorption by the increase in temperature could not be responsible for sorption-desorption hysteresis because the isotherms of sorption and desorption decrease simultaneously and may still overlap. Conversely, sorption by chemical interactions (e.g., amidation reaction) is an endothermic process, while the corresponding desorption is an exothermic process. The increase in temperature could enhance chemical sorption and reduce the desorption of organic compounds by soils, changing the sorption-desorption equilibrium to be sorption-favorable. For example, the sorption of aniline by carbonaceous sorbents was significantly enhanced by increasing temperature. The increase of chemical sorption by increasing temperature probably could enhance sorption-desorption hysteresis, because sorption through chemical bonds could not be released in the desorption process. For example, the sorption-desorption hysteresis of aniline by carbonaceous sorbents increased with the increase in temperature from 10 °C to 40 °C (Wu et al., 2013). The rubbery state of SOM can be changed to the glassy state by increasing the temperature once it exceeds the glassy transition temperature of SOM. Sorption of AOCs by SOM in the rubbery state is reversible, while sorption by SOM in glassy state is irreversible. Therefore, the irreversible sorption of AOCs by SOM with glassy structure could be changed to reversible sorption by an increase in temperature that exceeds the glassy transition temperature. For example, the significant sorption-desorption hysteresis of 1,2,4-trichlorobenzene by a Pahokee peat disappeared as the temperature increased from room temperature to 91 °C (Sander and Pignatello, 2007).

Ionic strength

The influences of ionic strength on sorption and desorption of AOCs by soils mainly relate to three aspects: (i) effect on the structure of SOM; (ii) salting-out effects for AOCs; (iii) competition with AOCs for sorption. Wu and Sun (2010) reported that the sorption-desorption hysteresis of phenanthrene by a soil and a sediment were both weakened as the ionic strength increased from 100 $\mu\text{g L}^{-1}$ to 500 $\mu\text{g L}^{-1}$. They proposed that a higher ionic strength could compress humic substances to a more condensed form and decrease the size of voids in humic materials by electrostriction which is responsible for the sorption-desorption hysteresis of organic compounds (Wu and Sun, 2010). Kan et al. observed that the irreversible fraction of sorbed naphthalene increased with the increase of ionic strength from 0.05 M to 1.0 M, due to the blocking of micropores in soils and sediments by the flocculation of clay (Kan et al., 1994). The flocculation tendency of clay was positively correlated with ionic strength. Qiu et al. reported that the sorption-desorption hysteresis of tetrachloroethylene by soils was weakened as the ionic strength increased from 0.01 M to 0.5 M, and proposed that higher ionic strength could induce salting-out effects and transform more tetrachloroethylene from the aqueous to solid phase in the rubbery state, enhancing reversible sorption and reducing sorption-desorption hysteresis (Qiu et al., 2016). Sorption of ionic AOCs by soils through electrostatic interactions could be reduced by the increase of ionic strength due to competition in ion exchange, while desorption could be enhanced. However, the change of sorption-desorption hysteresis depends on the reversibility of sorption derived from electrostatic interactions. Hysteresis could be reduced if the weakened sorption by ionic strength is irreversible, whereas it could be unchanged or enhanced if the weakened sorption by ionic strength is reversible.

pH

The influences of solution pH on sorption and desorption of AOCs by soils could be mainly through altering the packed structure of SOM, the physiochemical properties of AOCs, and subsequently the sorptive interactions of AOCs with SOM. Humic substances could be regarded as supramolecular associations of self-assembling small molecules, which are stabilized by weak interactions such as hydrophobic interactions, electrostatic interactions and hydrogen-bonding interactions (Piccolo, 2001). The dissociation of functional groups (e.g., $-\text{COOH}$, $-\text{OH}$, $-\text{NH}_2$) of humic substances largely depends on the solution pH. At low pH, humic substances are tightly packed by the strong intermolecular hydrogen-bonding interactions. With increasing pH, the formation of hydrogen-bonding interactions is prevented by the dissociation of functional groups, leaving the surface molecules of humic substances detached. At high pH, the functional groups of humic substances are fully negatively charged by deprotonation, which try to locate as far as possible from each other because of strong electrostatic repulsion and make the humic substances loosely packed. Similar to humic substances, the dissociation of functional groups of ionizable AOCs (e.g., $-\text{COOH}$, $-\text{OH}$, $-\text{NH}_2$) is also largely determined by the solution pH, which could influence the irreversible interactions between AOCs and SOM and subsequently the sorption-desorption hysteresis. For example, at neutral or high pH, the amino groups of organic compounds are not dissociated and could form amide bonds with carboxyl groups of SOM, inducing significant sorption-desorption hysteresis. However, at low pH, the amino groups are dissociated and can no longer form the amide bonds, resulting in the disappearance of sorption-desorption hysteresis. Therefore, solution pH could affect irreversible pore deformation through altering the structure of SOM and irreversible sorption interactions through changing the degree of dissociation of SOM and AOCs.

Co-solutes

In the real environment of soils, different kinds of AOCs commonly co-exist, resulting in competitive sorption of different AOCs by soils. When the sorption system was diluted by a fresh solution to initiate desorption, sorption-desorption hysteresis was probably enhanced due to the 'competitor dilution effect'. The concentration of co-solute in the desorption process of a target solute is less

Fig. 10 Sorption-desorption isotherms for benzene by a wood charcoal with the coexistence of toluene at various initial concentrations (C_0). Reproduced with permission from Sander M and Pignatello JJ (2007) On the reversibility of sorption to black carbon: Distinguishing true hysteresis from artificial hysteresis caused by dilution of a competing adsorbate. *Environmental Science & Technology* 41: 843–849.

than that in the sorption process, resulting in the different pathways for sorption and desorption. In the sorption system, the co-solute with a higher concentration could occupy more sorption sites and reduce the sorption of a target solute to a greater extent. In the desorption system, the co-solute with a lower concentration could weaken the sorption of a target solute to a lesser extent. Therefore, the desorption branch of isotherms for a target solute should be higher than the sorption branch, i.e., significant sorption-desorption hysteresis. Moreover, the hysteresis should be positively correlated with the initial concentration of the co-solute, because dilution could induce a greater difference in concentration for the co-solute with a higher initial concentration in the sorption and desorption systems, i.e., the greater difference between sorption and desorption pathways for a target solute. For example, Sander and Pignatello reported that hysteresis was not observed for the single-solute sorption-desorption of benzene, toluene and nitrobenzene by a wood charcoal, but hysteresis was observed in the bi-solute sorption-desorption system and enhanced with the increasing concentration of the co-solute (Fig. 10) (Sander and Pignatello, 2007).

Conclusion

Soil organic matter (SOM) including humic substances and black carbon are mainly responsible for the sorption-desorption hysteresis of AOCs in soils. There are three possible mechanisms that could explain the sorption-desorption hysteresis, i.e., (i) irreversible pore dilation or pore creation, (ii) formation of closed interstitial space and entrapment of organic molecules, and (iii) formation of irreversible sorptive interactions. The SOM with glassy structure (e.g., humic substances in a glassy state and black carbon with moderate pyrolysis temperature) could induce significant sorption-desorption hysteresis, due to limited flexibility of the glassy structure and irreversible pore deformation of glassy structure. However, the SOM with rubbery structure (e.g., humic substances in rubbery state and black carbon with low pyrolysis temperature) did not result in hysteresis because of the highly flexible rubbery structure and reversible pore deformation. The SOM with fixed-porous structure (e.g., black carbon with high pyrolysis temperature) did not lead to hysteresis either because of inflexibility of the fixed-porous structure and the absence of pore deformation. Sorption-desorption hysteresis was frequently observed for AOCs with larger molecular sizes, which could induce longer equilibrium time and more irreversible pore deformation of SOM, and also for AOCs with functional groups due to the formation of irreversible sorptive interactions with SOM. Environmental effects such as temperature, ionic strength, solution pH and competitive co-solute could significantly affect sorption-desorption hysteresis, mainly through creating different pathways for sorption and desorption. This knowledge is crucial for predicting the migration, transformation and bioavailability of AOCs in soils and assessing the potential risks to the environment and public health.

Abstract

Soil surface charge exerts strong control over the adsorption of ions from the soil solution, colloidal stability and particle aggregation, and rates of mineral dissolution. There are multiple methods for quantifying surface charge including proton titrations and measurements of surface excess of charged ions. These methods can be used to determine the pH values where one or more components of surface charge vanishes (i.e., points of zero charge).

Glossary

Adsorbate Matter accumulating at the interface between adsorbent and the aqueous phase.

Adsorbed ion charge density (Δq) The net charge density created by adsorption of ions, other than H^+ and OH^- , into inner-sphere complexes, outer-sphere complexes, and the diffuse ion swarm.

Adsorbent The solid surface on which matter accumulates.

Adsorption The net accumulation of matter at the adsorbent surface.

Diffuse layer surface-charge density (σ_d) The net surface charge density created by adsorbed ions in the diffuse layer.

Inner-sphere complex surface-charge density (σ_{is}) The net charge density created by ions adsorbed via direct coordination to surface functional groups (i.e., with no water molecules interposed between adsorbate and surface).

Intrinsic surface-charge density (σ_{in}) The sum of structural and proton surface charge densities.

Outer-sphere complex surface-charge density (σ_{os}) The net charge density created by adsorption of hydrated ions that form stable complexes with adsorbent surface functional groups.

Point of zero charge The pH value at which particle surface charge is equal to zero.

Point of zero net charge The pH value at which adsorbed ion charge density is equal to zero.

Point of zero net proton charge The pH value at which proton surface charge density is equal to zero.

Proton surface-charge density (σ_H) Surface-charge density created by the formation of adsorption complexes involving proton or hydroxide ions as adsorbate; the difference between surface excess of protons and hydroxide ions ($\sigma_H = q_H - q_{OH}$).

Structural surface-charge density (σ_0) Surface-charge density created by isomorphic substitutions among ions of differing valence in the crystal structure of an adsorbent.

Key points

- Inorganic and organic soil particles exhibit “a balance of surface charge” wherein charge resulting from isomorphic substitutions within mineral structures and from complexation of ions in inner- or outer-sphere surface complexes is balanced by ions adsorbed in a diffuse ion swarm.
- Both organic and inorganic particles contain ionizable functional groups that undergo protonation and proton dissociation as a function of pH.
- In addition to protons, other dissolved ions can also form surface complexes, which, in turn, alters particle surface charge.
- On the basis of surface charge balance, we can denote several “points of zero charge” that are quite useful to predicting the behavior of adsorption–desorption reactions in soil.
- The objective of this chapter is to utilize the principal of surface charge balance to review reactions governing particle surface chemistry and associated points of zero charge.

Introduction

Many soil chemical reactions occur at the interface between solid particles and the aqueous phase. Fundamental to the reactivity of this interface is the surface charge on soil particles, which affects a range of chemical phenomena including adsorption of charged solutes, the nature and extent of the electrical double layer on soil particles, kinetics of colloid aggregation, and mineral dissolution rates. **Cation and anion exchange capacities**—which influence the retention of plant-available nutrients, as well as the immobilization of metal(loid) contaminants, such as arsenic (As) and lead (Pb) (Karna et al., 2018)—are directly affected by the nature of soil surface charge and its response to changes in solution of chemical properties such as pH, ionic strength, and ion composition.

Charge properties have traditionally been used to characterize soils as “permanent” or “variable” charge media. These characterizations reflect the relative predominance of one or more soil solid-phase constituents. The surface chemistry of permanent charge soils is governed by isomorphically substituted mineral particles (i.e., 2:1 layer-type clays such as **smectite** and vermiculite), whereas **variable-charge soils** are dominated by amphoteric hydroxylated surfaces (i.e., **metal oxides**, hydroxides or oxyhydroxides, and organic matter). As a result of the ubiquity of hydroxylated solids in soil environments, all soils have some portion of their total surface charge that is conditional upon aqueous chemical conditions.

The law of surface-charge balance states that, irrespective of the source of particle surface charge, it must be balanced by the net accumulation of ions in the surrounding diffuse **swarm** (Sposito, 2016). The balance of surface charge and relationships among components may be used to constrain the application of molecular models to the particle–water interface and to verify internal consistency of adsorption measurements. Particularly useful in this respect are points of zero charge, which define the physico-chemical conditions wherein one or several components of surface charge sum to zero.

Components of surface charge

Electric charge develops on soil particle surfaces as a result of: (1) structural disorder or isomorphous substitutions among ions of differing valence within **soil minerals**, and (2) reactions of surface functional groups with ionic species in **aqueous solution**. These mechanisms of charge development are incorporated into four “components of surface charge” that together contribute to the “total particle surface-charge density,” σ_P . Surface-charge density is conventionally expressed in coulombs per square meter, consistent with the **International System of Units** (SI). For complex solids, including soils, charge is likely to be distributed unequally among the many phases present, owing to differences in structural charge, surface site density, and specific surface area. Furthermore, measurement of total surface area alone is nontrivial and method-dependent. For these reasons, soil charge is often measured on a mass basis and expressed as moles of charge per kilogram. Values presented in each of these sets of units differ by the factor F/a_s , where F is the Faraday constant and a_s is specific surface area.

The “net structural surface-charge density,” σ_0 , is created by isomorphous substitutions in soil minerals. These substitutions occur in both primary and secondary minerals, but they produce significant surface charge only in the 2:1 layer-type **aluminosilicates** (e.g., Fig. 1). The “net proton surface-charge density,” σ_H , results from the difference between the moles of protons and the moles of hydroxide ions complexed by surface functional groups (Fig. 2). The “net inner-sphere complex surface-charge density,” σ_{IS} , results from the net total charge of ions, other than H^+ (hydrogen) and OH^- (hydroxyl), which are bound into inner-sphere surface coordination. Inner-sphere complexation involves the formation of one or more direct bonds between the adsorbate molecule and adsorbent surface functional group, with no water molecules interposed (Fig. 3a). The “net outer-sphere complex surface-charge density,” σ_{OS} , results from the net total charge of ions, other than H^+ and OH^- , which are bound into outer-sphere surface coordination. Outer-sphere complexes involve hydration water interposed between the adsorbate and the adsorbent surface (Fig. 3b). The net total particle surface charge is the sum of these four components:

$$\sigma_P = \sigma_0 + \sigma_H + \sigma_{IS} + \sigma_{OS} \quad (1)$$

The right side of Eq. (1) indicates contributions to particle surface charge from both permanent (σ_0) and conditional (σ_H , σ_{IS} , σ_{OS}) components; the value of σ_0 depends only upon the composition and structure of the solid phase, while the values of the remaining components depend upon the nature of both the solid and solution phases. The last two terms on the right side of Eq. (1) together define adsorbed ions that are immobilized in surface complexes, also known as the “Stern-layer charge,” σ_S .

Surface charge balance

Aqueous particle suspensions are electrically neutral. Therefore, if σ_P is nonzero, it must be balanced by a diffuse **swarm** of **ion charge** equal in magnitude but opposite in sign to σ_P . These ions differ from those bound into the Stern layer because their much greater mobility relative to the adsorbent surface is analogous to diffusive motions of free ions in **aqueous solution**. The net charge of such ions defines the “diffuse layer surface-charge density,” σ_d . The charge balance equation for soil particles may then be written:

$$\sigma_P = -\sigma_d \quad (2)$$

Fig. 1 Isomorphic substitution of ions of differing valence gives rise to structural charge density (σ_0) that is independent of solution chemistry. Model structures of vermiculite (a) and smectite (b) show that substitutions (small white spheres) can give rise to charge in the (a) tetrahedral (Al^{3+} (aluminum) for Si^{4+} (silicon) substitution) or (b) octahedral (e.g., Mg^{2+} (magnesium) for Al^{3+} substitution) sheets of 2:1 layer-type silicates. The location of substitution, particularly in regard to proximity to the surface, affects site reactivity. Large white spheres, O; black spheres, Si; gray spheres, Al; hatched spheres, OH.

Fig. 2 Development of proton surface-charge density (σ_H) derives from the net adsorption of protons on particle surfaces and reflects the Brønsted acid–base chemistry of surface functional groups. PZNPC, point of zero net proton charge.

and substituting the left side of Eq. (1) into Eq. (2) gives:

$$\sigma_0 + \sigma_H + \sigma_{\text{IS}} + \sigma_{\text{OS}} + \sigma_d = 0 \quad (3)$$

The terms σ_{IS} , σ_{OS} , and σ_d correspond to different molecular mechanisms of ion adsorption that are difficult to distinguish on the basis of quantitative macroscopic measurements. These three terms in Eq. (3) together give the “adsorbed ion charge density,” Δq , which is the net charge of ions, other than H^+ and OH^- , adsorbed at the soil–water interface (Fig. 4):

$$\Delta q = \sigma_{\text{IS}} + \sigma_{\text{OS}} + \sigma_d = q_+ - q_- \quad (4)$$

Fig. 3 Surface coordination of ions in stable complexes results in the development of (a) inner-sphere complex surface-charge density (σ_{IS}) and (b) outer-sphere complex surface charge density (σ_{OS}), both of which contribute to total particle surface charge. Isomorphous substitutions, are shown schematically as gray spheres. (Cu, copper; Cs, cesium; P, phosphorus; F, fluorine; Na, sodium; Cl, chloride; Ca, calcium).

Fig. 4 The net charge deriving from adsorption of ions (other than H^+ and OH^-) in surface complexes ($\sigma_{IS} + \sigma_{OS}$) plus the diffuse ion swarm (σ_d) constitute the net adsorbed ion charge density (Δq). PZNC, point of zero net charge.

The value of Δq in Eq. (4) can be determined by measuring the difference between “surface excess” of cation charge (q_+ corresponding to all cations other than H^+) and “surface excess” of anion charge (q_- corresponding to all anions other than OH^-). The charge balance may then be rewritten as:

$$\sigma_0 + \sigma_H + \Delta q = 0 \quad (5)$$

Points of zero charge

Points of zero charge are defined most commonly as pH values for which one or more of the surface-charge components is equal to zero at a given temperature, pressure, and aqueous solution composition. The emphasis on pH derives from the wide and dynamic range of proton concentrations in soil solutions, and the fact that complexation of H^+ and OH^- at the surfaces of soil particles strongly affects the adsorption of other cations and anions (e.g., see Fig. 4 and Eq. (5)). Although pH will be used to illustrate points of zero charge here, it is important to note that one can also define them in terms of aqueous concentrations of other surface complexing ions, such as $H_2PO_4^-$ (phosphoric acid) or Pb^{2+} (lead) (Fig. 3a), which can affect the value of σ_P directly. Three principal points of zero charge are named conventionally as: (1) the “point of zero charge” (PZC), (2) the “point of zero net proton charge” (PZNPC), and (3) the “point of zero net charge” (PZNC).

Point of zero charge

The PZC ($\sigma_P = 0$) is defined as the pH value at which the net total particle surface charge, σ_P , is equal to zero. According to Eq. (2), σ_d also vanishes at the PZC, so that all adsorbed ions (other than H^+ and OH^-) must be bound into surface complexes. Traditionally, the PZC has been assessed by measuring the pH value at which soil particles exhibit zero electrophoretic mobility (i.e., the isoelectric point or IEP), assuming that a negligible portion of the diffuse ion swarm is advected during the electrophoresis measurement. Model calculations suggest that surface charge heterogeneity or patchiness can also result in a nonzero electrophoretic mobility for a particle whose overall charge is equal to zero. Values of PZC for soil minerals derived dominantly from electrophoresis measurements are presented in Table 1.

According to the DLVO (Derjugin–Landau–Verwey–Overbeek) theory, a suspension of colloidal particles should undergo rapid flocculation when net charge in the diffuse ion swarm (σ_d) is reduced to zero. Therefore, the PZC may also be determined by measuring the pH where a colloidal suspension of particles undergoes rapid coagulation (flocculation). However, the influence of

surface-charge heterogeneity probably affects collision efficiency as well. Methods involving the use of scanning force microscopy (e.g., [Stack et al., 2001](#)) are useful for elucidating patchwise heterogeneity of surface charge and providing direct force measurements of the PZC (e.g., as used to obtain the value of PZC for [quartz](#) in [Table 1](#)). Such methods have also been applied to characterize the surface charge heterogeneity of clay minerals ([Guo and Yu, 2017](#)).

Point of zero net proton charge

The pH value at which the proton surface-charge density, σ_H , is zero defines the PZNPC. Proton surface-charge density is given by:

$$\sigma_H = q_H - q_{OH} \quad (6)$$

where q_H and q_{OH} are the surface excess (e.g., in moles of charge per kilogram) of H^+ and OH^- , respectively. Therefore, at the PZNPC the moles of surface-adsorbed H^+ and OH^- are balanced. Proton and hydroxide adsorption reactions can be represented by the mass action expressions:

where SOH is a neutral surface hydroxyl group on a soil particle, and s, aq, and l represent the solid, aqueous, and liquid phases, respectively. If proton adsorption–desorption is assumed to occur dominantly at hydroxylated sites (e.g., as in the case of pure metal oxides), then the PZNPC defines the condition where the density or concentration of protonated sites is equal to that of proton-dissociated sites [i.e., $(SOH_2^+) = (SO^-)$]. Thus, both protonated and proton-dissociated sites can coexist at the PZNPC.

In “indifferent” electrolyte solutions (i.e., those comprising monovalent cations and anions that do not form stable complexes at particle surfaces), proton adsorption behavior, as depicted in [Fig. 2](#), is a function of the Brönsted acidity of surface functional groups. Soil particles exhibit a wide range in surface acidity, as indicated by the PZNPC values shown in [Table 1](#). Low PZNPC values are typical of more strongly acidic soil constituents such as silica, quartz, Mn (manganese) oxides, and natural organic matter, whereas higher values are observed for (hydr)oxides of Fe (iron) and Al. [Table 1](#) shows PZNPC values of soil minerals suspended in indifferent electrolyte solutions. However, the presence of cations (anions) that form inner- or outer-sphere surface complexes ([Fig. 3a](#)) will tend to decrease (increase) the PZNPC because of adsorptive competition with H^+ (OH^-).

Proton- and hydroxide-promoted dissolution of soil minerals is found to increase at pH values both below and above the PZNPC. Correlations are observed between dissolution rate constants and the absolute magnitude of σ_H , suggesting that metal–oxygen bonds at the particle surface are weakened as reactions in [\(7a\)](#), [\(7b\)](#) proceed to the right.

Point of zero net charge

The first two terms in [Eq. \(5\)](#) are often combined to provide a measure of “intrinsic surface-charge density,” σ_{in} , which derives from the crystal and surface structure of the adsorbent:

$$\sigma_{in} = \sigma_0 + \sigma_H \quad (8)$$

The PZNC is the pH value at which σ_{in} is equal to zero. The intrinsic surface charge is balanced by the adsorption of ions. Since σ_{in} results from both proton adsorption–desorption reactions (pH-dependent) and isomorphic substitutions, it comprises conditional and permanent components ([Fig. 4](#)). Since $\sigma_{in} = -\Delta q$, the PZNC may be determined: (1) by measuring the pH where surface excess values of cation and anion charge are equal (i.e., $\Delta q = 0$), or (2) by measuring the pH where $\sigma_0 = -\sigma_H$.

Charge balance dictates that, as σ_H decreases with increasing pH (affected by mass action as indicated in [Eqs. \(7a\)](#) and [\(7b\)](#)), ion adsorption–desorption reactions must balance the change in intrinsic charge density. The dependence of σ_H on pH is shown schematically in [Fig. 2](#), and corresponding effects on Δq are illustrated in [Fig. 4](#). For a soil adsorbent that is devoid of structural charge (i.e., $\sigma_0 \approx 0$), such as a highly weathered [Oxisol](#) that contains a negligible quantity of 2:1 layer-type [silicates](#), $\Delta q = -\sigma_H$, and the PZNPC equals the PZNC ([Fig. 5](#), top). This is also the case for pure oxides and hydroxides that are free of structural defects. The presence of negative structural charge ($\sigma_0 < 0$), which occurs because of isomorphic substitutions in many [temperate-zone](#) soils, results in the PZNC being less than PZNPC, and the value of Δq (or σ_H) at the PZNPC (PZNC) is equal to $-\sigma_0$ ([Fig. 5](#), middle). Positive structural charge ($\sigma_0 > 0$) is rare in soils, whereas it is detectable when PZNPC is less than PZNC, and its magnitude is given by the value of Δq (or σ_H) at the PZNPC (PZNC) ([Fig. 5](#), bottom).

In addition to the effects of σ_0 , the nature of variable-charge behavior, such as that depicted in [Fig. 5](#), is highly dependent on the Brönsted acidity—i.e., the proton affinity and adsorption–desorption behavior of the soil particles. For example, the magnitude and pH range of greatest local slope (i.e., $\delta\sigma_H/\delta pH$ or $\delta\Delta q/\delta pH$) depends on the identity and quantity of surface sites undergoing proton adsorption–desorption reactions. Whereas oxides and hydroxides of Fe and Al are weakly acidic, with PZNPC values near neutrality, more strongly acidic groups such as those residing on natural organic matter functional groups (e.g., carboxylic acids), silica or quartz surfaces, and Mn oxide surfaces all tend to decrease PZNPC values for whole soils.

The surface-charge balance of [Eq. \(5\)](#) is summarized in [Fig. 6](#); a plot of Δq vs σ_H should be linear with a slope equal to -1 , and x and y intercepts equal to $-\sigma_0$. The x and y scales in [Fig. 6](#) are arbitrary and actual values depend on surface chemistry of the

Fig. 5 The inverse relation between σ_H and Δq is depicted schematically for (a) $\sigma_0 = 0$ (PZNC = PZNPC), (b) $\sigma_0 < 0$ (PZNC < PZNPC), and (c) $\sigma_0 > 0$ (PZNC > PZNPC). The PZNC is indicated by gray arrows and the PZNPC is indicated by black arrows. PZNC, point of zero net charge; PZNPC, point of zero net proton charge.

Fig. 6 Surface-charge balance dictates that a plot of Δq vs σ_H must be linear, with a slope equal to -1 and x and y intercepts equal to $-\sigma_0$. PZNPC, point of zero net proton charge; PZNC, point of zero net charge.

adsorbent and the units selected for plotting surface-charge data (e.g., moles of charge per kilogram or coulombs per square meter). Curves such as those depicted in Fig. 5 (with pH as independent variable) are strongly affected by ionic strength and electrolyte composition for a given adsorbent, whereas the relation depicted in Fig. 6 must be reproducible for a given soil, irrespective of changes in solution chemistry.

Conclusions

When conducted rigorously, wet chemical methods, such as proton titration and ion adsorption, can be used to quantify the surface charge behavior of heterogeneous soil suspensions. In so far as natural soils are a multi-component mixture of minerals and organic matter, the charge properties characterized in this way are necessarily an average over all constituents. Hence, under a given set of solution conditions (pH, ionic strength and aqueous ion composition), different types of particles (with different extents of isomorphic substitutions and Bronsted acidities) exhibit different surface charge characteristics, for which the bulk charge is being measured. Conversely, surface force and atomic force microscopies have been employed to quantify the distribution of surface charge across individual particles, thereby greatly increasing the spatial resolution of the method. Future work should focus on interpreting the macroscopic behavior of soils, e.g., bulk surface charge and colloid aggregation behavior, as influenced by the charge properties of the individual constituent particles.

Abstract

Clay dispersion (deflocculation) and flocculation are fundamental phenomena in soils. Clay dispersion or flocculation depends mainly on clay mineralogy, soil solution ionic strength and pH, and the composition of the exchangeable cations. Various attraction and repulsion forces take place concurrently between clay particles and the balance between them dictates whether dispersion or flocculation occurs. In the case of the latter, different modes for clay particles association may take place. Monovalent cations (e.g., Na⁺) enhance clay dispersion whereas divalent ones (e.g., Ca⁺⁺) enhance flocculation. The sensitivity of soil clay systems to dispersive behavior is usually significantly greater than that of pure clay systems. Dispersion of soil clay particles alter soil pore size distribution and adversely affect soil hydraulic properties.

Key points

- Clay dispersion (deflocculation) and flocculation play a central role in determining soil physical and hydraulic properties.
- The balance between the repulsion and attraction forces acting simultaneously on clay particles determines the stability of the clay suspension.
- The electrical double layer thickness depends on the counter ion valence and the ionic strength of the bulk solution.
- Critical flocculation concentrations depend on clay mineralogy, pH, type of electrolyte and ionic strength.
- Spontaneous clay dispersion often takes place when sodic clay is placed in water of very low electrolyte concentration, yet upon increasing the latter, external mechanical force is needed to force dispersion.

Introduction

The clay particles of soils are of colloid size (less than 2 μm equivalent spherical diameter—Stokes' law) and usually carry a net negative charge. This charge is neutralized by exchangeable cations. The interaction between soil solution and soil clay and the phenomena of clay dispersion and flocculation depends on the type and amount of the soil clays, the nature of the exchangeable cations, and the electrolyte concentration in the soil solution (Shainberg and Letey, 1984). Clay dispersion (deflocculation) and flocculation are very important in determining the physical properties of soils such as hydraulic conductivity, aggregate stability, crusting, infiltration rate, and erosion (e.g., Quirk, 1994).

In a stable clay suspension, dispersed particles collide frequently because of their Brownian motion but separate again because of diffuse double-layer repulsion forces. When salt is added to the clay suspension, the particles may stick together upon collision, forming flocs that settle. The stability of the colloidal suspension is a balance between repulsive and attractive forces acting simultaneously among the suspended particles (Rengasamy and Sumner, 1998; Goldberg et al., 2012).

Shape and charge of soil clays

The clay minerals of most soils are dominated by various layer silicates. Layer silicate clay minerals are classified as 1:1 where each layer consists of one tetrahedral silica sheet and one octahedral alumina sheet (e.g., kaolinite); 2:1 where each layer consists of one octahedral sheet sandwiched between two tetrahedral sheets (e.g., montmorillonite and vermiculite); or 2:1:1 where a metal hydroxide sheet is sandwiched between the 2:1 layers (chlorite).

The clay minerals are characterized by isomorphic substitution of lower-valence cations in either the tetrahedral (Al replacing Si) or octahedral (Mg replacing Al) sheets or both. This excess of permanent negative charge inside the crystal is balanced by exchangeable cations on the external surface. Layer silicate clay minerals also possess variable charge located at the broken edges of clay minerals. At the edges of the 2:1 clay minerals, hydroxyl Al or hydroxyl Si is present. Negative charge may develop on the edges of the octahedral (Al—OH) layer at high pH and positive charge at low pH (Stul and Mortier, 1974).

The colloidal activities of the clay minerals depend on their specific surface area (with units of meters squared per gram) and the charge density expressed by their cation exchange capacity (CEC, in centimoles of cation charge per kilogram) divided by their specific surface area. Kaolinite is a widespread, 1:1 clay mineral with low CEC ($1\text{--}10\text{ cmol}_c\text{ kg}^{-1}$), small specific surface area ($20\text{--}50\text{ m}^2\text{ g}^{-1}$), and a low level of colloidal activity. Conversely, montmorillonite, the dominant clay in soils from semiarid regions, belongs to the 2:1 clay mineral category, has a large CEC ($80\text{--}120\text{ cmol}_c\text{ kg}^{-1}$) and specific surface area ($800\text{ m}^2\text{ g}^{-1}$) and a high level of colloidal activity. Vermiculite with large CEC ($120\text{--}150\text{ cmol}_c\text{ kg}^{-1}$) but intermediate surface area and illite with intermediate CEC ($20\text{--}40\text{ cmol}_c\text{ kg}^{-1}$) and surface area are clay minerals with low-to-intermediate colloidal activity (Goldberg et al., 2012). The mineralogy, charge characteristics, and CEC of several clay minerals, reported by Goldberg et al. (1999), are presented in Table 1.

Forces between clay platelets

Repulsion forces

The electrical double layer

According to the Gouy–Chapman theory, the diffuse double layer consists of the lattice charge and the compensating counter ions (Babcock, 1963). The counter ions are subject to two opposing tendencies: the cations are attracted electrostatically to the negatively charged clay surface; and the cations tend to diffuse from the surface of the particle, where their concentration is high, into the bulk of the solution, where their concentration is lower (Van Olphen, 1977). The two opposing tendencies result in decreasing counterion concentration from the clay surface to the bulk solution (Fig. 1). Divalent cations are attracted to the surface with a force twice as large as that of monovalent cations. Thus, the diffuse double layer in the divalent ion system is more compressed toward the surface. With an increase in the electrolyte concentration in the bulk solution, the tendency of the counterions to diffuse away from the surface is diminished and the diffuse double layer compresses toward the surface. The distribution of mono- and divalent cations in the diffuse double layer at high and low electrolyte concentration is also presented in Fig. 1.

In Gouy–Chapman's diffuse double-layer theory, the counter ions are considered as point charges without dimensions. As long as the ions are far from the clay surface, their concentration is small and their size has little influence on the statistical calculations of the diffuse double layer. However, in the vicinity of the clay surface, where the concentration of the cations is relatively large, the distance of closest approach to the surface is important, and the size of the ions and the energy of hydration of the cations must be considered to give an accurate description of the distribution of counterions near the clay surface. Consequently, the double layer is

Table 1 Charge characteristics and cation exchange capacities of clay minerals.

divided into the Stern layer, i.e., the first layer of the counterions immediately next to the clay surface, and the Gouy layer, which is the diffuse layer. Adsorbed cations are classified as being in the diffuse or Stern layer depending on their dimension and hydration energy (Van Olphen, 1977). Calculations using the amended theory predict differences in the adsorption characteristics and flocculation values of Li^+ , Na^+ , and K^+ montmorillonite in general agreement with experimental observations.

When two clay platelets approach each other, their diffuse counterion atmospheres overlap. Work must be performed to overcome the electrical repulsion forces between the two positively charged ionic atmospheres. The electrical double-layer repulsion force, also called the 'swelling pressure,' can be calculated by means of the diffuse double-layer theory (Goldberg et al., 2012). The greater the compression of the ionic atmosphere toward the clay surface, the smaller the overlap of atmospheres for a given distance between particles. Consequently, the repulsion forces between the particles decrease with increases in the salt concentration and in the valence of the adsorbed ions. Thus, a high level of repulsion and swelling persist in dilute solutions of sodium clay (Rengasamy and Sumner, 1998; Van Olphen, 1977).

Hydration repulsion forces

The adsorbed cations and the clay surfaces must lose some of their hydration water, because the clay particles approach each other very closely in the process of flocculation. The work that is needed to remove these water molecules manifests itself as the repulsion energy. Relative to the double-layer repulsion forces, the range of these forces is short. These forces partially negate van der Waals forces of attraction, resulting in particles not being trapped at a true primary minimum. This makes it easier for particles to disperse with little input of energy as the electrolyte concentration is reduced (Van Olphen, 1977; Shainberg and Kemper, 1996).

Flocculation and attraction forces

A stable clay suspension flocculates upon the addition of salt. Flocculation takes place only when a threshold electrolyte concentration, the 'flocculation value' (FV), is applied (Hunter, 1987). A suspension of clay platelets flocculates in three possible modes of particle association (Fig. 2): (1) association between flat oxygen planes of two parallel platelets (face to face, FF); (2) association between edge surface of neighboring particles (edge to edge, EE); and (3) association between edge and oxygen planar surface (edge to surface, EF) (Van Olphen, 1977; Goldberg et al., 2012). In the presence of small concentrations of NaCl, the diffuse double-layer repulsion prevents particle association and a stable suspension is obtained. As the concentration of NaCl increases, double layers at soil surfaces become compressed and, at the FV, attraction forces may prevail and EF, EE, and FF association may occur (Van Olphen, 1977). Similarly, when polyvalent cations are adsorbed (e.g., Ca and Mg) on the clay surface, the diffuse double layer is compressed and attraction forces may prevail (Quirk and Schofield, 1955). Although the three types of association are really three modes of flocculation, only the EE and the EF types of association were discussed in the past and were labeled clay flocculation with high gel volume. The thicker particles, which result from simple FF association, were not called 'flocs,' because they were condensed with low gel volume. Special cases of FF association, which lead to high-volume flocs, have now been described (Fig. 3) and it has been concluded that FF association may also lead to high-volume flocculation (Keren et al., 1988).

Van der Waals force of attraction

The van der Waals attractive force between colloidal particles arises from the fluctuating dipole of one atom that polarizes another, and the two atoms attract each other. This attraction between atom pairs is additive and therefore the energy of interaction between particles decreases much more slowly with distance than that between individual atoms. The van der Waals attraction force leads to FF clay association (Israelachvili, 1992).

Electrostatic EF attraction forces

The flat surfaces are not the only surfaces of the plate-like clay particles; they also expose an edge surface area. At the edges, the octahedral alumina or iron sheets are disrupted and primary bonds are broken. This situation is analogous to that on the surface of alumina or iron particles in alumina (Al_2O_3), and iron sols. On such surfaces an electric double layer is created by the adsorption of potential-determining ions. The hydroxyl-aluminum edge carries a positive charge in acid solution and a negative charge in high-pH solution. The point of zero charge (pzc) does not necessarily occur at neutral pH. The charge becomes more positive with decreasing pH, and its sign may be reversed with increasing pH. When the charge on the edges is positive and the repulsive diffuse double-layer forces are diminished by a high concentration of electrolytes, a positive edge to negative-face surface predominates and EF flocculation occurs (Keren et al., 1988; Quirk, 1994).

Clay charge density and electrostatic attraction forces

The colloid properties of clays depend to a large extent on the density of charge on the clay surface, that in turn affects the electrostatic attractions forces between the clay colloids. Numerous detailed discussions on this issue can be found in the literature (e.g., Keren et al., 1988; Rengasamy and Sumner, 1998; Goldberg et al., 2012 and references cited therein). Clay surfaces charge density can be derived from the exchange capacity per gram and the surface area per gram (Table 1). Sodium montmorillonite in dilute suspensions exists as single platelets. Calcium montmorillonite, even in distilled water, exists in packets (tactoids or quasicrystals), each consisting of several (4–9) clay platelets with a film of water 0.45 nm on each internal surface and c-spacing of less than 1.9 nm. The swelling pressure of calcium montmorillonite can be predicted from the diffuse double-layer theory if one assumes that the number of platelets in a tactoid is 5 and that only the Ca ions on the external surfaces of the tactoids form a diffuse double layer. Sodium, magnesium, and calcium vermiculite do not swell beyond 1.5 nm (two molecular layers of water between the platelets), even in distilled water. The illites exist in quasicrystals with c-spacing of less than 1 nm regardless of the adsorbed cations. It has been suggested that electrostatic attraction forces, which increase with the increase in surface charge density and with increase in cation valence, prevent swelling in clays with high surface charge density.

The charge density at clay surfaces is an average value, and heterogeneity of the charge density due to isomorphous substitution has been determined for montmorillonites ranging between 0.7×10^{-3} and $1.5 \times 10^{-3} \text{ mmol}_c \text{ m}^{-2}$. Wyoming bentonite is the most heterogeneous among six various clay types. It is possible, therefore, that at specific sites on the planar surfaces the charge density is very low or even zero (the surface area of these particular sites may not be detected). Thus, in the extreme situation where the charge density is very low (or even zero, such as in pyrophyllite), there are no repulsion forces (both double layer and hydration), and the van der Waals attraction forces exceed the repulsion forces and an FF association may occur (Fig. 3). Similarly, in sites where the charge density is large (such as in vermiculite), the electrostatic attraction forces between the cations and the clay platelets are also very high, swelling decreases, and an FF association may occur (Fig. 3). Since the montmorillonite platelets are long and flexible and able to bend, the platelets may form cohesive junctions at several locations of low or high surface charge densities to form a network structure, as illustrated in Fig. 3. This results in a high gel volume, as demonstrated for Na-montmorillonite at pH 9.8 (Fig. 4).

Spontaneous and mechanical dispersion

Spontaneous dispersion often takes place without energy inputs when sodic clay is placed in water at very small electrolyte concentration. The proportion of clay particles separated in this way increases with an increase in the sodium adsorption ratio (SAR) of the soil solution and with a decrease in the electrolyte concentration (Rengasamy and Sumner, 1998).

Hydrated clay particles in equilibrium with low-SAR solution, which have undergone limited separation, can be pushed further apart by applying external mechanical pressure such as stirring or raindrop impact. When the SAR of the clay solution is low to moderate and the electrolyte concentration is large enough to prevent spontaneous dispersion, the introduction of a mechanical force, such as mixing the suspension, may cause clay dispersion (Shainberg and Levy, 2005). The clay at the soil surface is especially susceptible to dispersion because of the mechanical energy applied by raindrops (Agassi et al., 1981). This is one of the reasons why the soil surface is more susceptible to clay dispersion and aggregate disintegration by low sodic conditions, compared with deeper in the soil profile.

Flocculation and dispersion in Na or Ca clays

Adsorbed Na ions form a diffuse double layer at the clay surface, and, because of the high swelling between the platelets, single platelets tend to persist in dilute solution. When salt is added to the clay suspension, the particles stick together upon collision, forming flocs that settle (Oster et al., 1980; Goldberg et al., 2012). The suspension is then separated into the bottom sediment and a particle-free supernatant liquid. The FVs of clays depend on counterion valency. The FVs of sodium and calcium montmorillonite

Boca Raton, FL: CRC Press; Oster JD, Shainberg I, and Wood JD (1980) Flocculation value and gel structure of Na/Ca montmorillonite and illite suspensions. *Soil Science Society of America Journal* 44: 955–959.

are 12 $\text{mmol}_c \text{L}^{-1}$ NaCl and 0.25 $\text{mmol}_c \text{L}^{-1}$ CaCl_2 , respectively (Table 2). The sodium montmorillonite gel has approximately 330 g of water per gram of clay, which corresponds to a film thickness of 440 nm per surface (Fig. 4). This thickness exceeds the range of diffuse double-layer or van der Waals forces. The open structure, typical of sodium montmorillonite gels, suggests that EF attraction forces or the flexible platelets mechanisms (Fig. 3) are operating (Keren et al., 1988).

Effect of pH on the FV of sodium montmorillonite

The FV of sodium montmorillonite by NaCl is pH dependent and its value is 12.6 $\text{mmol}_c \text{L}^{-1}$ at pH 7, and 10, 13, 31, and 44 $\text{mmol}_c \text{L}^{-1}$ of NaCl at pH 5, 7.5, 8.5, and 9.8, respectively (Fig. 4). The final gel volume of sodium montmorillonite samples at the above pH values is large (350–490 g of water per gram of clay) (Fig. 4). The large gel volume indicates that a three-dimensional ‘card house’ structure is formed, even at pH 9.8, in spite of the fact that at pH 9.8 a negative charge predominates at the broken edges. This considerable gel volume at pH 9.8 suggests that an open structure with FF association between the platelets (at sites of low and high charge density) predominates rather than the EF card house structure (Keren et al., 1988; Goldberg et al., 2012).

Dispersion and flocculation in Na or Ca clay systems

Whereas single platelets tend to persist in a dilute solution of sodium montmorillonite, calcium montmorillonite platelets aggregate into tactoids or quasicrystals. Each tactoid consists of several (4–9) clay platelets in parallel array, with interplatelet distances of 0.9 nm. A diffuse double layer exists only on the external surfaces of the tactoids. In a suspension containing a mixture of Na and Ca ions, 'demixing' of the cations occurs so that some interlayer spaces contain mainly Na ions and others mainly Ca ions (Shainberg and Letey, 1984). An indication of the location of the adsorbed ions in montmorillonite clay saturated with a mixture of mono- and divalent cations is obtained by measurements of the electrophoretic mobility of clay particles in suspension (Bar-On et al., 1970). A slight addition of exchangeable Na (e.g., 10%) to Ca-saturated clay has a considerable effect on the electrophoretic mobility of the clay (Fig. 5). When the exchangeable sodium percentage (ESP) in a clay suspension is less than 40%, the Na ions concentrate on the external surfaces of the tactoids and the Ca ions concentrate on the internal surfaces (Shainberg and Letey, 1984).

Results of studies of the FVs of montmorillonite and illite suspensions saturated with mixtures of Na and Ca ions in the exchange phase (Fig. 6) indicate that a small addition of exchangeable Na to Ca-saturated montmorillonite can have a considerable effect on the FV (Oster et al., 1980). Similarly, when the ESP of the clay suspension reaches 50, the electrophoretic mobility of the Na-Ca mixture reached that of pure sodium montmorillonite (Fig. 5). Also, the gel volume increases with an increase in SAR until it reaches the gel volume of pure sodium montmorillonite at SAR 50 (Fig. 7). The demixing model, which suggests that Na ions concentrate on the external surfaces of the tactoids and increase the flocculation values of the clay considerably, can be used to explain these results (Shainberg and Letey, 1984). Yet in clay suspensions with ESP of more than 50, disintegration of the tactoids is complete and single platelets predominate (Shainberg and Letey, 1984).

The effect of peptizing agents on dispersion

Sodium polymetaphosphate $((\text{NaPO}_3)_{13})$ is a very effective peptizing agent. Organic anions may also act as peptizing agents. The FV of peptizer-treated clay suspensions increases rapidly with increasing peptizer concentration. The anions are probably chemisorbed at the edges of the clay particles by reacting with the exposed Al. Thus, the charge of the edges becomes negative, which prevents the EF bond from taking place (Frenkel et al., 1992). If the EF bond is eliminated by the adsorption of polymetaphosphate, then one might expect that the open, card-house structure of the gel is also eliminated. However, an open structure with large gel volume has been obtained for the sodium gel (Table 3). This also indicates that an FF bond may lead to open gel structure (Van Olphen, 1977; Shainberg and Letey, 1984).

Soil clay systems

Flocculation and dispersion behavior of soil clays differs significantly from that of pure clay systems, possibly because soil clays usually occur as mixtures and because of their association with other minerals and organic matter present in the soil. A few studies demonstrate that the FV values of soil clays is two- to tenfold higher than for pure clay systems (Frenkel et al., 1992; Fig. 8). Conversely, in the presence of hydrous oxides or sparingly soluble minerals such as CaCO_3 , clay dispersivity is reported to be less severe (Oster and Shainberg, 1979). Hence, extrapolation from pure clay systems is of limited practical value.

Dispersion and the hydraulic properties of soils

Shainberg and Oster (1978) highlighted the importance of clay dispersion and movement in determining the hydraulic conductivity of soils. In this experiment a noncalcareous loam with 20% clay (montmorillonite) and a calcareous clay soil (50%, montmorillonitic) were equilibrated with a solution of $20 \text{ mmol}_c \text{ L}^{-1}$ with a SAR of 10 to give soils with an ESP of 10. Following equilibration, the soils were leached with distilled water. The loam was completely sealed and the clay soil maintained a relative hydraulic conductivity of about 20% (Fig. 9). This observation contradicts the generalization that soils having a greater content of expansive clays are more susceptible to sodic conditions because of more swelling. In the calcareous clay soil, salt concentration in the soil solution was maintained at $4 \text{ mmol}_c \text{ L}^{-1}$ by dissolution of carbonates. At ESP 10, this concentration prevents clay dispersion, and the hydraulic conductivity decrease is due only to swelling. Conversely, in the noncalcareous loam, soil solution concentration was below $1 \text{ mmol}_c \text{ L}^{-1}$, thus clay dispersion occurred and the dispersed clay clogged the conducting pores (Shainberg and Oster, 1978).

The infiltration rate of the soil surface, exposed to rain, is more susceptible to dispersion and sodic conditions than the hydraulic conductivity of the soils (Fig. 10). Furthermore, the infiltration rates of calcareous and noncalcareous soils are equally sensitive to low levels of exchangeable sodium (Kazman et al., 1983), whereas the hydraulic conductivity of the calcareous soils is less sensitive to low ESP than that of the noncalcareous soils (Shainberg and Oster, 1978). Both phenomena are explained by the clay-dispersion mechanism. At the soil surface, the concentration of the soil solution is determined solely by rain water and the low concentration of the salt enhances clay dispersion. Also, the impact of raindrops enhances clay dispersion. Both mechanisms enhance clay dispersion, aggregate disintegration, low infiltration rate, and high runoff (Shainberg and Letey, 1984).

Summary

The dispersion and flocculation of clays depend on the mineralogy of the clay and are affected by the composition of exchangeable cations, by the concentration of salt, by pH, by the presence of peptizing agents, and by the application of a stirring mechanism. In a mixed Na-Ca suspension, the flocculation value of the clay increases sharply with the introduction of a small amount of sodium and with an increase in pH. Dispersion, movement, and deposition of soil colloids alter the geometry of soil pores and affect the hydraulic properties of soils. Thus, introducing a small amount of Na to soils exposed to leaching with rainwater may cause clay dispersion and a deterioration of soil physical properties.

Abstract

Soil organic carbon (SOC) constitutes the largest carbon (C) stock in terrestrial ecosystems, and a rigorous understanding of the key processes involved in SOC dynamics is vital for soil fertility, soil health and a climate change mitigation strategy. Here, we review (i) the balance between C input and output, i.e., stabilization vs mineralization, which are fundamental processes upon which C content in soils ultimately depends; (ii) the controlling factors of SOC formation and decomposition, e.g., the climate, and physical, chemical and biological soil properties. Finally, classic and cutting-edge methods such as biomarker and isotope tools that are applied in SOC studies are introduced, and, the outlook for future research related to SOC is provided.

Key points

- Carbon (C) enters the soil from autotrophic microbes and plant photosynthesis.
- Gain of plant derived C in soil is by physical transfer and microbial necromass.
- C is lost to the atmosphere by microbial mineralization.
- New substrate-C induces native SOC priming by co-metabolism.
- SOC (Soil organic C) content is determined by the C balance between sequestration and losses (i.e., stabilization vs mineralization).
- Changes in C content and composition affect multiple physical, chemical and biological soil properties.
- The processes of mineralization involve both abiotic and biotic factors, including substrate recalcitrance, the soil matrix and the microbial community.

- The role of organisms, including bacteria, fungi, protists, nematodes, collembola, and earthworms, in decomposition are discussed.
- Classification of SOC into POM (particulate OM) and MAOM (mineral associated OM) advances our conceptual understanding of the biophysical mechanisms underpinning SOM turnover,
- Fungal aggregate–mineral interactions underlying carbon stabilization.
- Approaches of biomarkers and isotopes applied in SOC studies are introduced.

Introduction

Soil organic matter (SOM) is a key indicator of soil fertility and health, and changes in it will inevitably affect multiple physical, chemical and biological soil properties, including soil structure, nutrient availability, and biological activity and diversity. Soil organic carbon (SOC) constitutes the largest carbon (C) stock in terrestrial ecosystems, accounting for more than 1500 Pg C globally. Global SOC storage to a soil depth of 1 m is double the atmospheric C pool and treble the vegetation C pool. A critical component of global C sequestration is to increase SOC storage. Increasing SOC accumulation in terrestrial ecosystems is of vital importance for addressing the major challenge of global climate change resulting from increasing atmospheric CO₂ concentrations.

Soil organic C stocks involve the balance between two processes: (i) C enters the soil from plant-derived photosynthesis, and (ii) C is lost to the atmosphere by microbial mineralization (Fig. 1). The gain and loss of C are fundamental processes upon which all maintenance of life and C sequestration in soils ultimately depends. The SOC content is determined by the C balance between sequestration and losses (i.e., stabilization vs mineralization). A rigorous understanding of the key processes involved in SOC stabilization (e.g., entombing effects) and mineralization (e.g., priming effects) is vital for managing SOC pools as a strategy for climate change mitigation.

Decomposition and factors

The processes of mineralization involve both abiotic and biotic factors, including substrate recalcitrance, the soil matrix and microbial community (Lehmann and Kleber, 2015).

Fig. 1 Soil organic carbon stocks depend on the balance between carbon input (EE: entombing effects) and output (PE: priming effects). The SOC dynamics involves three phases, (i) balanced stage: C enters the soil from autotrophic microbes and plant photosynthesis equal to C loss via plant and microbial respiration; (ii) priming effects dominant stage: larger loss of new C and native SOC through microbial utilization and priming due to co-metabolisms; and (iii) entombing dominant stage: larger gain of C in soil via physical transfer, excreted metabolites, and microbial necromass.

Recalcitrance of chemical compounds

Soil organic C is largely a structurally unquantified pool, comprising random condensation products of microbial metabolites. While it has no clearly defined chemical structure, it can be characterized operationally as labile (available for microorganism metabolism) and recalcitrant (resistant to microbial degradation) components. For example, litter decomposition depends on the complexity and bioavailability of organic substances as well as the functional groups. As decomposition proceeds, soluble components are lost followed by the depolymerization of free cellulose and hemicellulose. Finally, the acid unhydrolyzable (AUR) fraction, considered a proxy for lignin and lignin-encrusted cellulose, starts to mineralize. Simple molecules, such as glucose can be degraded within minutes, whereas complex macromolecules containing covalent bonds between hemicellulose and lignin are slowly mineralized over months to years.

Low-molecular-weight organic substances

Numerous studies have investigated the microbial community response to plant-derived low-molecular-weight organic substances (LMWOS). Microorganisms in the rhizosphere have distinct substrate preferences in their responses and utilization of contrasting LMWOS as characterized by enzyme activities. Although the incorporation of plant-derived compounds (sugar, lipids, etc.) in soil has been widely studied, the identity of microorganisms that are stimulated by LMWOS and their metabolic processes remain poorly described. The stable-isotope probing combined with DNA is an effective tool for identifying microbial activities and functions in tracing the fate of LMWOS, such as glucose, methanol, p-hydroxybenzoic acid and propionate.

Recalcitrant compounds (cellulose, lignin)

Lignin is highly resistant to degradation due to its structural complexity. Yet, it can still be utilized by selected microbial communities, particularly some specialized fungi. The phylum Basidiomycota is associated with the decomposition of lignin. Complex and recalcitrant compounds in plant residues, such as lignin and cellulose, are not readily available for bacterial decomposition, whereas fungi release extracellular hydrolytic and oxidative enzymes that target specific structural polymers resulting in smaller, more “bacterially accessible” products. Specifically, the cellulolytic and ligninolytic capacities of the microbial community are responsible for the decomposition of cellulose and lignin, respectively. Crawford et al. (1977) showed that ^{14}C -labeled cellulose decomposed four times as fast as lignin. Real-time PCR was used to follow the abundance of genes and coding for cellobiohydrolases (*cbhI*) and lignobiohydrolases (*lcc*) identified that the phylum Ascomycota was gradually replaced by Basidiomycota during the decomposition process; the latter being able to synthesize enzymes to degrade polymers of lignin.

Pyrogenic organic matter

Pyrogenic organic matter (PyOM), the product of pyrolyzed organic materials, has drawn extensive attention as a promising material to enhance C sequestration because of their resistance to degradation. In the case of wildfires, alteration of the physico-chemical structure of plant-derived C to highly condensed polyaromatic organic matter promotes C sequestration in post-fire forest soils. Even though PyOM is relatively stable, it can still be partially mineralized. The decomposition of biochar was relatively rapid during the first 3 months following its incorporation into soils, but slowed considerably during the following 3.2 years. The initial soil CO_2 immediately following PyOM is often considered to be derived from the mineralization of labile components and often short-lived. The intensity of the CO_2 efflux is closely related to the physicochemical characteristics of PyOM, which were largely dependent on feedstock type and pyrolysis temperature. Differences in pyrolysis temperatures result in variation in PyOM chemical structure and composition, which largely explains biochar stability and rates of C mineralization in soil. The PyOM often has a greater abundance of recalcitrant components (aromatic density) with increasing pyrolysis temperature, making them more recalcitrant to microbial decomposition.

Although PyOM increases the SOC content, it promotes contradictory effects on non-biochar C dynamics, such as (i) interacting with plant-derived C (rhizodeposits;), and (ii) causing loss or gain of native SOC. Following PyOM amendment to soil, both negative priming effects (PEs, i.e., decreased CO_2 release) and positive PEs (i.e., increased CO_2 release) have been reported. Positive PEs in particular are of concern because they offset the C sequestration effects of PyOM additions. The mechanisms involved in PyOM-induced SOC mineralization are attributed to shifts in the soil microbial community through changes in abiotic variables, such as acid neutralization via increasing soil pH (Luo et al., 2017). Microbial biomass, activity and enzyme production were increased in the charosphere, the interface between the PyOM and bulk soil, and can be largely ascribed to (i) improved microbial habitat afforded by the large porosity and surface area of PyOM, and (ii) increased supply of labile organic components or other nutrients contained within biochar resulting in stimulation of the microbial community.

Role of organisms in decomposition

Organic substances in soils annually release an estimated 58 Pg C into the atmosphere through microbial decomposition. To underpin microbial community dynamics during litter or straw decomposition, it is crucial to elucidate the underlying mechanisms by which organic residues affect soil C sequestration. Understanding microbial communities and their utilization of rhizo-C and litter and straw is crucial for optimizing the sequestration of photosynthesized-C inputs into soils.

Bacteria and fungi

Straw and litter are model plant-derived substrates containing lignin, cellulose and hemicellulose. Decomposition of the primary constituents of straw is a complex process that depends on a progression of decomposers as decomposition proceeds. The diversity of bacteria and fungi, often regarded as the major drivers for decomposition of the labile and recalcitrant fractions of plant residues, have been frequently monitored throughout the decomposition process. Complex and recalcitrant compounds in plant residues, such as lignin and cellulose are not readily available for bacterial decomposition, whereas fungi release extracellular hydrolytic and oxidative enzymes that target specific structural polymers, thereby creating smaller, more “bacterially accessible” products. Microbial succession with a shifting enzymatic production exerted a positive effect on litter decomposition. For example, soft-rot fungi are common in the early stages of decomposition, whereas white- and brown-rot fungi dominate in the later stages. Endophytic fungi were regarded as weak decomposers that preferentially utilized the relatively labile organic matter fraction at the early stage of decomposition, whereas ectomycorrhizal fungi became dominant at later stages.

Fungi are among the most widely distributed organisms on earth and are of great environmental importance. Fungi are ubiquitous in soils, and dominate in soils with large organic matter content and acidic pH values, but constitute a smaller proportion of the microbial community in intensively managed mineral soils. Many fungi are free-living in soil, whereas others form parasitic or symbiotic relationships with plants or animals. Fungi are involved in a multitude of functional roles, such as decomposition, nutrient acquisition and mineral weathering. Previous studies confirmed the important role of fungi in the biodegradation of amended organic matter, e.g., plant litter.

Mycorrhizal fungi are known to be associated with plants, as it helps plant to obtain nutrients, while benefits from root-released organic substrates for C and energy. Arbuscular mycorrhiza fungi (AMF) are widely reported to play an important role in plant nutrient uptake, as well as the mineralization of root derived C. The AMF also increase the mineralization of SOC through a rhizosphere priming effect, which can be attributed to the widespread spatial distribution of rhizodeposits and extended area to obtain nutrients. For example, AMF help plants and themselves to exploit N through SOM mineralization (i.e., N-mining), when soils are nutrient deficient that cannot meet nutrient stoichiometric requirements (Jeewani et al., 2021b).

Fauna (protist, nematodes, collembola, earthworms)

Soil meso- and macro-fauna are major drivers in the early decomposition phases, with physical fragmentation of materials being a critical first step prior to mineralization by fungi and bacteria. Protists are increasingly recognized as key participants in multiple ecological processes, and important contributors to C turnover and transfer within soil food webs (Geisen et al., 2018). Soil protists can use rhizodeposit-C either through direct assimilation or by indirect predation. Soils harbor an enormously diverse and abundant protist population, most of which are considered major consumers of soil bacteria and fungi. These protist consumers influence C and nutrient flows across several trophic levels of soil food webs by preying on a wide range of bacteria and fungi. The diversity of trophic modes makes protists major participants of the soil microbial loop, which influences microbial biomass, activity and community structure in soil ecosystems. Protist predation, therefore, plays a significant role in microbial-driven decomposition.

Soil invertebrates (e.g., collembolan and earthworms) form a crucial part of the soil process related to the rates of decomposition of SOC and litter C. Soil mesofauna collembola alter the availability of organic matter, thereby indirectly mediating the primary decomposing microflora through trophic interactions. For instance, Yu et al. (2021) revealed the significant role of collembola in the degradation of maize (*Zea mays* L.) litter by increasing the C availability and shaping the community of decomposers, e.g., Ascomycota. Similarly, it has been suggested that earthworms modulate maize C mineralization by (i) changing the availability of C sources for primary decomposers and (ii) fragmenting and mixing these organic substances within the upper soil horizons. Earthworms also affect antagonistic interactions within the microbial community, particularly fungal groups.

Formation of SOM

Genesis and pathways

Plant-derived vs microbially-derived organic matter

Plant root-derived C dynamics in the rhizosphere are crucial for SOM formation and thus mitigation of greenhouse effects from increasing atmospheric CO₂ concentrations (Lehmann and Kleber, 2015). In general, C is transferred from the atmosphere to soil through plant photosynthesis and rhizodeposition in the form of water-soluble sugars and organic acids, and insoluble high-molecular-weight compounds.

Microbial necromass and its accumulation in soils

Microbial necromass (i.e., dead microbial biomass) is a significant source of SOM mainly because of recalcitrance of the cell walls, which have relatively long residence times in soil. The contribution of necromass to SOC content is far greater than previously considered, and was estimated to account for up to 40–80% of SOC (Liang et al., 2017).

Carbon flow through the atmosphere-plant-microbe-soil continuum

The microbial pathway through microbial biomass is poorly reflected in current climate models that incorporate SOC sequestration. An average of 0.54% of the ¹³C was found in microbial biomass carbon (MBC) immediately after ¹³CO₂ pulse labeling of flooded rice (*Oryza sativa* L.), and up to 0.41% remained in the MBC pool at the end of the growing season (Liu et al., 2019). The

$^{13}\text{CO}_2$ -pulse labeling and phospholipid fatty acids-stable isotope probing (PLFA-SIP) were used to quantify the allocation of photosynthetic C flows through plants shoots, roots, soil aggregates and the microbial community during ryegrass (*Lolium perenne* L.) elongation. Soil amended with biochar had decreased rhizodeposited- ^{13}C assimilation by fungi from 141 ng C g^{-1} soil to 33.6 ng C g^{-1} soil. The microbial pathway through necromass, however, has largely been ignored (Liang et al., 2017). Inclusion of microbial necromass into SOC sequestration models can help predictions of C storage in soil. Quite recently, a continuous $^{13}\text{CO}_2$ labeling study was conducted to trace C flows in the plant-microbe-soil necromass continuum, and the authors found that fungal necromass associated with soil mineral plays a significant role in soil C sequestration (Luo et al., 2021).

Abiotic drivers

Climate

Soil C cycling is regulated by soil microorganisms that in turn are strongly linked to climate variables. A temperature increase can enhance C loss in temperate forest soils by accelerating carbohydrate decomposition. Soil C cycling is further controlled by moisture conditions as regulated by precipitation, with CO_2 efflux and the metabolic respiration quotient increasing with increasing precipitation. Numerous investigations have reported rhizodeposit-driven C sequestration under various climate change scenarios. In general, soil C sequestration increases under elevated CO_2 (e CO_2) conditions. Rhizodeposits increased because e CO_2 -stimulated net primary production, shoot and root biomass, and increased the root/shoots ratio leading to increased rhizodeposited C inputs. By using continuous $^{13}\text{CO}_2$ labeling method, (Luo et al., 2018) found that rhizodeposits promote the accumulation of SOC under elevated CO_2 .

Soil characteristics

Herein, the broadly described soil abiotic factors that affect soil biotic properties and thus SOC dynamics include soil properties such as pH, mineral composition, nutrient composition. It has been widely reported that mineralization of root exudates, plant residues and pyrogenic C is affected by soil pH, mineral content, SOC and nutrient concentrations. This is mainly through changes in soil biotic properties and the regulation of the microbial community composition. For example, a meta-analysis based on 107 datasets from 64 long-term mineral fertilizer trials worldwide reported an average 15.1% increase in MBC mainly due to an increase in pH and nutrient contents (Geisseler and Scow, 2014). Numerous studies have confirmed that soil pH is one of the most influential factors affecting the biomass, activity and composition of the microbial community. Soil pH has a less profound effect on fungi than bacteria. Pietri and Brookes (2009) observed that fungal PLFAs were more dominant at lower pH values in the Hoosfield acid strip experiment at Rothamsted Research Station (across a uniform pH gradient due to a single chalk application during the 19th century).

Agricultural practices

The addition of organic matter amendments (e.g., straw, manure) has been demonstrated to be an effective practice in agro-ecosystems to build up SOC stocks to mitigate global CO_2 emissions. With large amounts of straw being incorporated into soils annually, the build-up of soil organic matter reached $0.35 \text{ t C ha}^{-1} \text{ yr}^{-1}$. This equates to a globally-scaled C sequestration potential for straw return of $34.4 \text{ Tg C yr}^{-1}$ (Minasny et al., 2017). A recent global meta-analysis based on 363 publications concluded that SOC content could be increased significantly on average by 14.9% through residue incorporation (Xia et al., 2018). Furthermore, a century-long field study at Rothamsted demonstrated the efficacy of building up SOM stocks through organic manure application.

Application of fertilizers affects substrate decomposition and may induce SOM mineralization (priming effects) as a result of a shift in the size of microbial biomass and structure of the microbial community. Nitrogen fertilizer application affected the accumulation of rhizodeposits in soil because of changes in the soil aggregate size fractions and shifts in the microbial community (Luo et al., 2018). Research on microbial responses to fertilization and consequent C dynamics are warranted.

Particulate organic matter and mineral associated organic matter

The formation of SOM is complex and largely depends on the input of plant-derived carbon and its transformation in the soil matrix. It is manifested by emerging evidence that SOM persistence mostly relies not only on C recalcitrance but also soil biophysical structures. These structures affect the microbial accessibility of organic matter that adheres on mineral surfaces or is protected by aggregates, as opposed to inherent chemical recalcitrance. Soil aggregates and mineral surfaces are often considered as hotspots for the production of biofilms by C-microbe-mineral interactions, leading to greater sequestration potential when additional C is added (Cotrufo and Lavelle, 2022). Classifying SOC into particulate organic matter (POM, mostly of plant origin) and mineral-associated organic matter (MAOM, mainly secondary minerals such as Al and Fe (hydr)oxides and layer silicate clays) advances our conceptual understanding of the biophysical mechanisms underpinning SOM turnover, namely stabilization via physical occlusion and chemical bonds, and mineralization through microbial utilization.

The efficiencies of POM and MAOM formation (% of C-inputs of rhizo-C, root and straw incorporated into each fraction) were quantified by isotopic techniques with rhizodeposits having the highest MAOM formation efficiency (46%). According to Six et al. (2002), both POM and MAOM are spatially linked from microaggregates to macroaggregates; While the fresh litter surfaces of POM concurrently promote the occlusion of organic matter into aggregates, the surfaces of MAOM acts as a nucleus in the formation of organo-mineral associations. Organo-mineral complexes are the basic components of aggregation and key to the persistence of organic matter. Less than 20% of the mineral surface area supported organic matter attachment sites, and most new inputs of organic

matter were attached to organo–mineral clusters already existing on the soil surface (Vogel et al., 2014). Therefore, the MAOM fraction is controlled by adsorption onto mineral surfaces with subsequent physical occlusion into microaggregates, whereas POM occurs either as a free (non-attached) fraction or is occluded into macroaggregates.

This physical hierarchy shapes niche differentiation for microbial assembly and subsequent organic matter transformations. The abundance and activity of microorganisms determine the transformation pathways for plant-derived C evolution into SOM. The microbiome is controlled by soil microsites within POM and MOAM, where biological, chemical and physical factors determine microbial community composition and metabolism. The microsites within POM and MOAC provide physical support for these biochemical processes through adsorption and desorption or complexation and dissolution making C sources available to colonized microorganisms. Mineral, such as kaolinite, ferrihydrite and quartz, host microbial communities by controlling microbial colonization on their surfaces. These minerals serve a foundational role in shaping the microbial community and thereby transformations of SOM. The adhesion of microorganisms to mineral and organic–mineral surfaces provides a fundamental basis for the underlying soil biogeochemical processes. Biotic factors mainly refer to the growth, activity, development, reproduction and metabolism of microorganisms, which are dependent on soil structure and C nutrient availability. The way that microorganisms, the key players in transforming plant-derived C into small molecules and subsequent humification, are controlled by the content of organic components (POM) and inorganic components (MAOM) offers a perspective about the mechanistic understanding of C stability.

Soil C sequestration potential in both POM and MAOM fractions is affected by vegetation (e.g., quality of C inputs), climate and soil properties including texture, mineralogy, pH, and microbial community structure. Chemical properties of plant-derived C inputs determine its distribution and transformation efficiency within these fractions. While the more recalcitrant compounds play a larger role in POM formation, the relatively simple compounds have a larger contribution to MAOM formation. For example, it was estimated that the formation efficiency by rhizodeposits compared with straw in agro-ecosystems to SOC formation was five times greater. This reflects the significance of MAOM in the accumulation of SOM from the input of low-molecular-weight compounds from plant rhizodeposits. In addition, compared to POM formation, MAOM formation requires nitrogen (N) and has a limited storage capacity when N availability is deficient. For instance, nitrogen-containing compounds that remain after the microbial metabolism of straw are preferentially fixed as mineral–organic complexes. This might reflect that (i) POM components from straw are usually lignin-like substances, and or (ii) the mineral-associated small molecules produced by microbial depolymerization are stoichiometrically limited.

Fungal aggregate–mineral interactions underlying carbon stabilization

The AMF promote rhizo-C stabilization by hyphae which induces soil aggregation and thus increases C storage (Averill et al., 2014). The AMF contribute to soil aggregate stability and aggregate formation by extra-radical hyphae, e.g., the genus *Glomus* transports plant-derived organic matter from roots to act as glue in forming soil aggregates by mineral–hyphal–aggregate interactions and or indirectly by altering biochemical properties of the soil–root environment.

Minerals protect SOC mainly through adsorption and or precipitation, with short-range-order phases and metal–organic complexes (Jeewani et al., 2020). Mineral such as goethite can promote Fe–organic complexes, which accelerate the formation of aggregates and influence both the processes and fate of rhizo-C and SOC (Jeewani et al., 2020, 2021a). These processes of SOC stabilization and mineralization driven by biotic–abiotic (hyphae–mineral) interactions occur simultaneously. The AMF and minerals can promote SOC sequestration through hyphae–aggregate–mineral interactions. Jeewani et al. (2021a) highlighted the contributions of both goethite (abiotic attributes) and AMF (biotic contributor) to C accrual in soil–plant systems. They found amendments of AMF and goethite resulted in a 0.6-fold decrease of rhizodeposit-derived CO₂, and an 11.3-fold larger allocation of rhizodeposits into macroaggregates. This was most likely due to SOC precipitation with goethite and macroaggregate formation stimulated by AMF hyphae. Further analyses by micron-scale Fourier transform infrared spectroscopy (μ -FTIR) showed that the spatial distribution of polysaccharides overlapped with Fe–O minerals within macroaggregates, supporting the concomitant processes of rhizodeposit stabilization and aggregate formation through hyphal–aggregate–mineral interactions.

Yet, these abiotic and biotic interactions via AMF, minerals and aggregates might have conflicting consequences on the SOC content. On the one hand, AMF might enhance microbial access to mineral-protected organic matter. The AMF have shown the potential to enhance the mobilization and mineralization of organic compounds associated with minerals. Further, it was reported that AMF help plants to obtain phosphorus from organic matter that is bound to goethite. This causes C loss through nutrient mining by microorganisms. On the other hand, AMF promote C stabilization by the (i) transfer of rhizodeposits to mineral surfaces (Averill et al., 2014), and (ii) creation of aggregates that promotes physical protection of organic matter by encapsulation or association with minerals (Six et al., 2002). These processes of SOC stabilization and mineralization driven by hyphae–mineral–aggregate interactions still require further investigation.

Approaches applied in SOC studies

Biomarkers

Soil organic matter inputs consist of partially-decomposed litter, root residues, rhizodeposits and microbial metabolites (Lehmann and Kleber, 2015). Establishing effective biomarkers that distinguish among these C sources and separate living microorganisms from dead microbial necromass is very challenging (Liang et al., 2017). Phospholipid fatty acid analysis combined with stable isotope probing can be used to trace plant-fixed C flows to the living microbial community in soil (Chen et al., 2021).

The accumulation of amino sugars in soil is a good indicator of dead microbial components, considering that plants do not produce amino sugars. Although more than 20 amino sugars have been identified in microorganisms, glucosamine (GlcN), galactosamine (GalN) and muramic acid (MurN) are the most widely used biomarkers. Glucosamine in soil is mainly derived from chitin originating in fungal cell walls, while MurN originates exclusively from bacterial cell walls. Thus, the relative amounts of glucosamine and muramic acid provide an indication of fungal (GlcN) and bacterial quantities (MurN), respectively (Liang et al., 2017).

Isotopic approaches

Tracing carbon flows and nutrient uptake isotopes

Carbon inputs through rhizodeposition are difficult to quantify because most measurements focus on the C pool size, which is relatively stable. Isotopic labeling techniques provide a tracer to track the flow and fate of photosynthesized-C through the plant-microbe-soil continuum. With isotopic labeling, it was estimated that ~45% of the photo-assimilates were distributed in plant shoots, 1–5% in roots and 0.2–3% were recovered in the soil organic C (SOC) pool, with 2–8% lost via belowground respiration. A dual labeling approach with ^{13}C and ^{15}N allows elucidation of C-N tradeoffs between the plant root and soil (Fu et al., 2021). For instance, biochar application increased ^{15}N uptake in plant shoots and leaves, but decreased rhizodeposited- ^{13}C recovery from large and small macroaggregates by 12–57% and 57–72%, respectively.

Partitioning soil CO₂ emissions among various C sources

To partition total CO₂ evolved from a single added substrate, a classic two-pool isotope mixing model has been widely used to partition among the two C sources, the added substrate and SOM. For instance, stable isotope techniques can distinguish C decomposition between substrate and SOC. However, quantitative partitioning between C sources using two stable isotopes (^{13}C and ^{12}C) has only been applied to two C systems. Separating among three C sources precisely, e.g., SOM, glucose and crop straw, is not possible using the two-pool model. It remains challenging to partition among three C sources, which are ubiquitous in natural systems, e.g., plant-soil contains rhizodeposits, litter, and SOC.

Recently, a dual radioactive- ^{14}C plus stable- ^{13}C labeling enabled the separation of three C sources (Luo et al., 2017). Radioactive ^{14}C is sensitive and precise, providing highly accurate measurements of partitioning among C pools and fluxes, and therefore, CO₂ from ^{14}C labeled substrate can be excluded first from the system. By using a mixed model twice the remaining C sources (^{13}C , ^{12}C) can be separated. In addition, Whitman and Lehmann (2015) introduced a dual-isotope approach which separate soil total CO₂ to SOC, biochar and root respiration. The development of more complex methodological approaches to discern among three C sources will provide several important advances to future research.

Outlook: New paradigms for SOC research

Recalcitrant nature of organic matter and microbial accessibility

A central paradigm of SOC mineralization is that the rate is controlled by either the nature of organic matter recalcitrance or microbial activity, abundance and community composition. It is posited that SOM mineralization mostly depends on the accessibility of soil microorganisms to SOM. Soil organic matter turnover is mainly governed by microbial accessibility rather than the recalcitrance of SOC. Thus, if SOC is not continuously converted to bioavailable and water soluble forms, or, microorganisms cannot move to the C sources, the mineralization of SOC would be at a very slow rate. With the importance of SOC mineralization to the overall C sequestration process, it is crucial to understand the dynamics of microbial biomass better in response to C source accessibility, which is most likely to be protected by abiotic factors such as physical occlusion or chemical precipitation.

Kemmitt et al. (2008) noted that even though 90% of microorganisms are destroyed by CHCl₃ (chloroform) fumigation of soil, following fumigant removal, SOC mineralization continued at the same rate as in the nonfumigated soil. They posited that mineralization of soil organic C is a two-stage process: non-bioavailable, humified forms are converted by abiotic processes to bioavailable forms which, only then, can undergo mineralization by the soil microbial biomass. Following this rationale, the former describes abiotic transformations of non-bioavailable SOC to bioaccessible and bioavailable forms, whereas the subsequent process is the biological mineralization of bioavailable SOC. They termed this concept the “regulatory gate hypothesis,” which explains why the mineralization of SOC proceeds at the same rate in both nonfumigated and fumigated soil, even though the size of the microbial population was decimated by fumigation, and both the microbial activity and diversity were drastically changed by fumigation. Brookes et al. (2017) demonstrated that the spatial arrangement of aggregate structure largely determined SOC bioaccessibility to consumers, providing additional support for the regulatory gate hypothesis. Their data indicated that SOC had first to undergo abiotic processes to become bioaccessible or bioavailable before it could be mineralized by the microbial biomass.

The precise nature of factors controlling the first may include processes such as adsorption and desorption, chemical oxidation and free radical activity. The biogeochemical cycling of organic substances depends on their interactions with the mineral soil matrix. The SOM can be stabilized on mineral surfaces and or inside aggregates during their formation, which protects the organic compounds from microbial degradation. Further, Jeewani et al. (2020) suggest that the sequestration of rhizodeposits in soil is via abiotic “rusty sink” (i.e., precipitation by iron oxide) and biotic mechanisms, e.g., microorganisms with branched filaments contributing to the development of aggregation.

Fig. 2 Changes in trait-based strategy by fertilizer regimes affecting carbon sequestration. Control signifies soil without fertilizer, NPK signifies soils with fertilizer application of nitrogen, phosphorus and potassium, and NPKM signifies soils with fertilizer application of NPK and manure.

Traits-based strategy

Soil organic carbon content is determined by the carbon balance between sequestration and losses (i.e., stabilization vs mineralization). These opposing processes respond to organic C additions by a microbial tradeoff between anabolic and catabolic metabolisms, which is central to understanding the role of environmental biology in C exchange. This requires a strategy shift from a solely taxon-based approach toward an assessment of metabolic strategies. This provides a new paradigm for research on microbially driven processes, with a particular focus on soil C dynamics. Yet, the link between microbial metabolism (i.e., tradeoff between catabolism and anabolism) and C sequestration (stabilization vs mineralization) remains elusive.

Microorganisms compete with one another to acquire C, energy and nutrients during C mineralization. Fierer et al. (2007) demonstrated that SOC mineralization depends on a microbial community shift between two microbial functional groups that differ in terms of their C-use traits: r-strategists and K-strategists. The r-strategists respond quickly to simple, labile C substances in resource abundant environments, whereas K-strategists breakdown complex biopolymers in resource limited environments. Therefore, SOC mineralization is a function of the balance between r- and K-strategists, which is underpinned by substrate recalcitrance, nutrient status and the prevailing environmental niche. Further, Malik et al. (2019) classified microorganisms into three main strategy groups according to combinations of resource availability and environmental stress response: Y-strategists (flourish in soils without stress and an abundance of resources), A-strategists (adapt to ambient stress and resource-limited environments) and S-strategists (adapt to stress in resource-abundant environments). Moreover, Anthony et al. (2020) demonstrated how microbial communities and their eco-physiology (e.g., microbial growth, metabolism, etc.) as shaped by environmental stress (e.g., acidity, salinity) influence C decomposition. Future research to elucidate how changes in soil physicochemical properties by climatic changes (i.e., eCO_2) or agriculture practices (i.e., fertilization) that lead to shifts in the dominance of Y, A and S-strategists will help decipher the integrated mechanisms underlying C decomposition and its sequestration potential in soils (Fig. 2).

Conclusion

Soil organic C constitutes the largest C stock in terrestrial ecosystems, and its accumulation in soil pool is of vital importance for addressing the challenge of increasing atmospheric CO_2 concentrations. Soil organic carbon stocks depend on the balance between carbon input and output. The factors controlling SOC formation and decomposition include soil structure, nutrient availability, and biological biomass, and community diversity. Specifically, the processes of mineralization involve both abiotic and biotic factors,

including substrate recalcitrance, the soil matrix and microbial community, while the microbe (necromass)–mineral–aggregate interactions addressed the underlying mechanisms underpinning SOC formation. The methods used in SOC studies and the outlook for future research were given to advance our understanding of the key processes involved in SOC dynamics, which is vital for soil fertility, C sequestration, soil health and a climate change mitigation strategy.

Abstract

Proteins are complex macromolecules and their three-dimensional structure determines their activity. They play essential roles in soil; they act as reserves of essential nutrients particularly C and N, as enzymes they determine the biogeochemical cycles of essential nutrients, as important components of soil organic matter, they contribute to soil physical stability. After a brief presentation of basic protein chemistry and a description of proteins in soil, including adsorption properties, extraction and characterization, case studies of enzymes, two potentially toxic proteins and a controversial protein known as glomalin-related soil protein are described. A final section presents the pitfalls of soil metaproteomics.

Key points

- Soil proteins are important components of soil organic matter
- They are strongly, quasi-irreversibly, adsorbed.
- Enzyme activity is strongly dependant on protein properties
- The persistence and biological properties of two potentially toxic proteins (insecticidal Bt proteins and prion proteins) are determined by interaction with soil organo–mineral surfaces.
- Soil metaproteomics has been hindered by the absence of robust methods to extract and purify proteins

Introduction

Proteins are macromolecules that play many roles in soil. Their properties depend on their three-dimensional structure that is strongly influenced by their interactions with soil organo–mineral, and organic components. An overview of the most important features of protein chemistry in soil is given, with emphasis on commonly encountered problems in the study and interpretation of protein interactions and biological activity in soil. Special attention is given to enzymes that control the biogeochemical cycles of major elements, to the controversial group of proteins known as glomalin-related soil protein and to two classes of proteins with potentially adverse properties, namely prion proteins and the insecticidal Cry or Bt-proteins. Finally the features of protein chemistry in soil that have to date limited the expansion of soil metaproteomics are considered.

Basic information on protein chemistry

Proteins are complex three-dimensional organic molecules composed of amino acids connected with peptide links ((Norde et al., 2012), and many standard text books). Typically they have molecular masses of tens of thousands of grams; smaller chains of amino acids comprising only tens of amino acids are generally referred to as peptides or oligopeptides. Protein mass is given with the unit Dalton (Da), defined as 1/12 of the mass of a carbon-12 atom, and thus almost equivalent to the gram. Proteins are the building blocks of living organisms and are therefore abundant in soils. The precise composition of a protein depends on the component amino acids but in general they contain about 53% C and 16% N. The other major component is oxygen, with much smaller amounts of phosphorus (P), sulfur (S) and other elements. The chemistry of proteins is determined not only by their amino acid

composition, but also by their 3-dimensional structure. The structure of proteins is defined at three levels: the primary structure is the sequence of amino acids; the secondary structure is the local organization of these amino acids forming, for example alpha helices and beta-sheets; the tertiary structure is the overall shape and size of the molecule, depending on salt bridges, hydrogen bonds and disulfide bonds. The native conformation of proteins is the most energetically favorable tertiary structure and depends not only upon the amino acid composition but also external factors such as temperature, pH, hydration and salt concentration. In aqueous solution proteins often have a hydrophobic core leaving hydrophilic groups exposed. Protein structure varies to minimize the energetic state depending on external conditions. The propensity to conformation change leads to the classification as hard or soft proteins: hard proteins resist conformational changes whereas soft proteins change conformation readily as a function of external conditions, including adsorption, which will be described later. Proteins are amphoteric, namely they contain both acidic and basic groups and so their charge is sensitive to pH. Even at their point of zero charge there will be positively and negatively charged patches. Finally, proteins may form oligomers and polymers, and the propensity to do so differs between proteins and depends on external conditions such as pH, ionic strength and temperature. If a protein solution becomes cloudy, then the presence of polymers is likely and the solution may be filtered or centrifuged to obtain a clear solution. However, clear solutions may contain a mixture of monomers and oligomers with different properties, including adsorption properties.

Proteins in soil

Proteins are ubiquitous in soils (Quiquampoix and Burns, 2007). They may be intracellular, existing within living or formerly living organisms, or may be extracellular after release by cell lysis or active exudation. Extracellular proteins are predominantly rapidly and strongly adsorbed on solid surfaces, including the organo-mineral surfaces of soils, therefore free extracellular proteins are uncommon in soil. Proteins play many roles in soil. They control the biogeochemical cycles of major elements such as C (carbon), N (nitrogen), P and S, both as enzymes and sources of these nutrient elements. Proteins, together with their constituent amino acids are reported to be the major chemical form of soil organic nitrogen (Schulten and Schnitzer, 1998; Rillig et al., 2007) and may comprise a non-negligible fraction of soil organic carbon. As with other organic molecules, proteins contribute to the stock of organic matter and the physical structure of soils. These aspects, however, have received little research attention, with the exception of glomalin-related soil proteins, which will be discussed later. By far the greatest research on soil proteins has been on the catalytic activity of soil enzymes. The understanding and prediction of the persistence of proteins in soil and the catalytic activity of enzymes in soil require consideration of the extent and consequences of adsorption.

Protein adsorption

The adsorption of proteins on many surfaces including soils and soil minerals has been widely studied (Norde et al., 2012 #27; Quiquampoix and Burns, 2007 #32). The most detailed studies have been carried out using well defined, clean surfaces and a single protein. Adsorption mechanisms and driving forces are more difficult to investigate in detail in soils, because of the complex heterogeneous surfaces and large number of proteins present. However studies of model systems are nevertheless pertinent to soil science.

Soils and their components have a large capacity for the adsorption of proteins. To some extent the capacity is determined by surface area. Adsorption capacity of proteins on various clean mineral and organic surfaces is of the order of mg m^{-2} . This means that adsorption capacity of up to g g^{-1} could be expected on clay-textured soils, as has been reported for Bt and prion proteins, for example (Helassa et al., 2011). Proteins appear to adsorb to form monolayers on surfaces and there is no evidence that proteins adsorb in multilayers. In theory proteins could form suprastructures on surfaces, but this has not been demonstrated. Adsorption isotherms tend to take the form of Langmuir isotherms, namely increasing adsorption with increasing concentration in solution until a maximum or plateau is reached. The mathematical form of the Langmuir isotherm was developed from the adsorption of ideal gases with assumptions about sorbent and surface interactions, however goodness of fit to a model does not imply that the underlying assumptions apply. Contrary to the assumptions of perfect gas adsorption, adsorption sites in soil are not identical; adsorbed protein molecules interact, and adsorption of proteins is not a dynamic reversible process. While many studies of protein adsorption in chemistry and colloid science focus on maximum adsorption, in soil science it is often not pertinent to consider maximum adsorption. In the case of enzyme adsorption, concentration and surface coverage are often orders of magnitude below the maximum surface coverage. It is therefore more precise to refer to affinity rather than capacity. Adsorption affinity is often assessed using the distribution coefficient, K_d , the ratio of adsorbed content to concentration in solution. Since the adsorption isotherm is non-linear, the average K_d value may be very different from the tangent to the adsorption isotherm, which reflects the affinity of the surface for an additional small amount of sorbent.

Adsorption at surfaces is very rapid, and within the limits of experimental observation, it may be considered to be instantaneous. Empirically observed adsorption kinetics can thus be ascribed to rate limiting access to adsorption sites, the break-up of aggregates exposing new surfaces, and possibly to a lesser extent conformational changes of the adsorbed protein favoring further adsorption. It has also been shown with clean, homogeneous surfaces that the conformation of molecules depends on surface coverage; as a surface is increasingly covered, additional proteins adsorbed later will tend to have smaller contact area with the surface. Proteins are

Fig. 1 Schematic representation of protein adsorption. (A) Protein adsorption, followed by (time-dependent) conformational change with spreading on the surface, thereby increasing contact area. (B) End-on packing on a surface; side-on packing with greater contact area and lower surface coverage; protein arriving at a nearly saturated surface forced to adopt an end-on contact. (C) Preferential adsorption of one protein (in blue) leaving a greater proportion of the other (red, hatched) in solution (D) Enzyme adsorbed with catalytic activity (substrate-to-product) conserved; catalytic activity reduced due to conformational change; catalytic activity lost due to conformational changes; active site oriented toward surface, thus not available for catalytic reaction.

not spherical, and adsorption may be end-on or side-on, depending on whether the longer axis is perpendicular or parallel to the surface (Fig. 1).

The driving forces for protein adsorption are complex; they include electrostatic interactions, hydrophobic interactions and hydrogen bonding. Conformational changes following adsorption involve changes in entropy. Protein structure may rearrange to present hydrophilic moieties to the solution, keeping hydrophobic moieties within the core of the protein or facing the surface. This can lead to adsorption isotherms that depend on the rate of addition of protein, namely the initial concentration in solution. A simple representation of this is to consider a large amount of protein brought in contact with a surface over a short period of time:

much protein would adsorb, with no time to spread out, whereas if protein is added more slowly, or in a step-wise fashion, the earliest adsorbed molecules spread, leaving less space for newer molecules to adsorb. Molecules reaching the surface later may thus either not adsorb, or adsorb with different conformation or orientation (Fig. 1). Conformational changes after adsorption also contribute to the apparently irreversible adsorption of proteins. These processes can also lead to a decrease with time of extractability or biological properties, that is difficult to distinguish from degradation (Fig. 1).

Protein adsorption on all surfaces is strongly pH dependant. This is true for charged surfaces as well as uncharged surfaces. In most cases a bell shaped curve is observed (Quiquampoix and Burns, 2007), with the largest adsorption capacity being near to the isoelectric point (iep), the pH at which net charge on the protein is zero, although both positively and negatively charged amino groups may be involved in adsorption. When net charge on the protein is opposite to that of the surface (positive at pH below the iep, in contact with electronegative surfaces) electrostatic interactions are strong, but other interactions cannot be ignored. At more alkaline pH there is nevertheless adsorption showing that some amino acids remain positively charged, and also that other interactions contribute to adsorption. Adsorption tends to decrease with increasing ionic strength, or salt concentration, in solution. This is in part due to a common ion effect, but also reflects the importance of electrostatic interactions on protein adsorption to charged organo-mineral surfaces.

Protein adsorption is usually calculated from the loss of protein from solution. When non-specific techniques are used for the quantification of protein, this may require unrealistically large concentrations of protein. Smaller amounts of adsorption can be quantified using a quartz crystal microbalance, that can also give information on the hydration properties of the adsorbed molecules, but this method cannot be used for soils. An alternative may be to label the protein, if a single protein is to be studied, with either a radioactive or fluorescent label. In both cases it is assumed that the presence of the label has no effect on the affinity of the protein for the surface, nor the subsequent conformational changes. This assumption is difficult to verify. In the case of enzymes, the change in catalytic activity in solution is measured, but the possible adsorption of inhibitors or activators from solution is usually overlooked.

Proteins also interact with colloidal or soluble organic molecules in soil. While this may not strictly be adsorption, the consequences may be similar on organo-mineral surfaces. The biological and biochemical properties may be modified, as observed for example with the loss of catalytic activity for enzymes in solutions of tannin or humic substances. It is often difficult to separate proteins and other soluble organic matter, as discussed later for the groups of proteins known as glomalin-related soil protein.

Study of adsorbed proteins

There is an abundant literature on the study of proteins adsorbed on surfaces (Norde and Lyklema, 2012). The practical applications of such research include the technological importance of immobilized enzymes, the fouling of medical materials and antigen binding to adsorbed antibodies. Methods are based on various techniques, a non exhaustive list includes vibrational spectroscopy, fluorescence spectroscopy, microscopy, optical methods, atomic composition obtained from X-ray photoelectron spectroscopy, hydrolysis followed by amino acid analysis and low temperature ashing, thermal analysis and surface physical properties such as hydrophobicity and wettability. However the large majority of these studies involve clean, uniform, often planar, surfaces, in marked contrast to the 'dirty' heterogeneous surfaces of soils. There are huge differences in the detail of information on protein structure for purified crystalline proteins, proteins adsorbed on clean well-defined surfaces, and adsorbed on soils. Mica, glass and quartz may be considered to be models of soil minerals, and are used for the methodologies that require planar surfaces. Vibrational spectroscopies, Raman and Fourier transform infra-red (FTIR) spectroscopies, have also been used to investigate the conformational changes of well-characterized proteins following adsorption on model clay minerals, such as montmorillonite. The investigation of adsorbed proteins in soil is therefore restricted to a limited range of experimental techniques, and much information is obtained on indirect evidence. These include the quantification of adsorption, kinetics of adsorption (although the rate limiting factors are certainly related to access to surfaces not the adsorption step), the conservation of biological and biochemical properties, pH-dependence of adsorption, and the persistence of the adsorbed protein. It is generally accepted that adsorption confers some degree of protection against microbial and catalytic breakdown. However some of this evidence is based on observations of loss of biological activity, whereas in reality the decline may be due to changes in conformation and orientation of adsorbed molecules. It is widely reported that immobilization changes the temperature dependence of catalytic reactions and the temperature stability of enzymes. This is important for the technological use of immobilized enzymes, and is also thought to be significant for soil enzymes. However in soil there is a more complex interplay between the synthesis, activity and persistence of enzymes produced by soil (micro)organisms.

Extraction, characterization and quantification of soil proteins

Extraction from soil is often the limiting step of the characterization and quantification of molecules and elements in soil. This is a huge obstacle to the study of soil proteins, and no methods are universally accepted (Greenfield et al., 2018). Extraction yields vary between soils, and depend on the protein and the protein-surface interaction, although this has never been investigated in depth. Extraction solutions are often adapted empirically from solutions used to extract proteins from biological material or used to clean surfaces. In general, alkaline pH and large salt concentration promote protein desorption. In addition, surfactants, or detergents,

may improve extraction yield, but may cause problems for the subsequent characterization or quantification of the proteins. Urea and guanidinium may also be used to disrupt hydrogen bonds. Proteins may also be removed from soil surfaces by heterogeneous exchange, namely the addition of other proteins. This is only appropriate when the added protein can be efficiently and specifically removed before further analysis, or if detection of the target protein is highly specific, for example when immune-assays are available. Extraction may alter protein structure and hence their biological or biochemical properties.

As described below, an operationally defined soil protein or group of soil proteins, known as glomalin-related soil protein, GRSP, or glomalin, is extracted by autoclaving in neutral or alkaline citrate solution. This technique extracts large amounts of protein, far in excess of the extraction yield at ambient temperature. However a drawback to the large extraction yield is the co-extraction of other substances. It has been suggested that strong, possibly covalent bonds are formed between proteins and other substances during the autoclave-extraction, making purification difficult.

Extraction yield may be calculated after controlled addition of a model protein to soil or to model minerals. However calculation of the extraction yield of native proteins from soil is limited by the lack of independent measurement of total protein present. It is only possible to compare the amounts of proteins removed by the use of different techniques. In general the amount of protein recovered is small compared with the probable content, given that proteins and amino acids are thought to be the primary forms of soil nitrogen. There is currently no evidence of the proportion of soil protein extracted, nor what relation there is between extraction efficiency and protein origin or composition. Studies of model proteins, including enzymes, Cry proteins or prion proteins, indicate that extractability decreases with time. It is therefore difficult to distinguish between extractability and decay.

After extraction, a range of techniques is available to quantify soil proteins. In a small number of cases highly specific, immune-tests are available and are subject to little interference. However in most cases, quantification is obtained using non-specific methods that may be subject to interference. Common protein quantification methods include UV-spectrometry (aromatic amino acids absorb at around 260 nm) and colorimetric assays. The most common colorimetric tests are Bradford, Lowry and the related bicinchoninic acid (BCA). They differ in the ease of experimental operation, their sensitivity to interference and their detection limits and working ranges. All these tests are based on chemical reactions with amino functional groups; the apparent protein concentration detected depends therefore on protein structure, the exposure of component amino acids to the solution containing chromophores, and the proteins used to calibrate the assay. The most convenient and therefore widely used test is the Bradford assay. However, this has a narrow working range and is sensitive to many of the reagents contained in common protein extraction cocktails, such as surfactants. Protocols for these methods are widely available in standard texts, research papers and in commercial documentation. However potential artifacts are widely overlooked by soil scientists; these include interference from non-protein solutes and the color of soil extracts.

Protein chemists and biochemists routinely clean up protein-containing solutions prior to quantification. The approaches routinely used are not always well adapted to soil science laboratories or to the impurities found in soil extracts. Acid precipitation is often reported for soil extracts even though it does not separate humic substances from proteins. Phenol extraction is often used by protein chemists but is unusual in soil science, and therefore is often found to be inconvenient.

Gel quantification is generally used to separate proteins to count the number of distinct proteins present in solution and may provide semi-quantitative assays. However inadequate sample purification can prevent the use of gel electrophoresis, with smeared gels that cannot be exploited. In the few published studies of soil proteins, the number of proteins separated is unreasonably small.

It is often not necessary to quantify soil proteins by chemical methods, since the biological or biochemical properties are of more importance than the absolute amount of protein present. It is therefore reasonable to study these properties without extraction. However when proteins are removed from the soil matrix before investigation, it must be remembered that they may have been denatured by the physical or chemical extraction method. There is never a simple, constant relation between biological, or biochemical, activity and amount of protein present.

Once in solution, chromatography may be used to separate proteins according to their size, hydrophobicity or charge. Amino acid composition, obtained by mass spectrometry after acid hydrolysis may give some information on the protein composition of soil organic matter. Although spectroscopic approaches are available to investigate protein composition and conformation in solution, the complexity of soil extracts limits their usefulness.

Soil enzymes

Many soil proteins are enzymes, and they probably compose the most studied class of soil proteins. These proteins dominate the biogeochemical cycles of important nutrients such as C, N, S and P. Many aspects of soil enzymes are treated in other chapters. However the protein nature of enzymes has important consequences on the performance and dynamics of enzymes. Extracellular enzymes are usually adsorbed on soil organo-mineral surfaces, and after adsorption they undergo conformational changes leading to changes in catalytic activity. Both the extent of adsorption and consequent conformational changes depend on both the enzyme and the surface. The complex, heterogeneous nature of soil organo-mineral surfaces and of the soil solution prevents precise prediction of the extent of adsorption and conformational changes of soil enzymes. Soil solution typically contains components that may activate or inhibit catalytic activity (Gianfreda and Bollag, 1994; Allison, 2006). The soil chemical property that has the greatest influence on catalytic activity is pH.

Soil catalytic activity is usually measured by adding model substrates and assaying the amount of a single product after a relatively short period. Since enzyme activity is strongly substrate dependent, the reported activity can at best be considered to be

potential activity (Nannipieri et al., 2012, 2018). For this reason there is often weak correlation between given catalytic activity for different substrates, for example fluorescent and colorimetric chromophores. In addition there is also weak correlation between measured catalytic activity and longer term assessment of the targeted biogeochemical function, such as organic residue turnover. It is therefore not correct to assume a direct positive relation between the amount of enzyme present and measured catalytic activity.

Nevertheless, because of the important roles of catalytic activity in soil, they are widely studied. In general, catalytic activity is measured with no attempt to desorb enzymes from soil. This is because of the difficulty of removing enzymes, like other proteins, from the soil organo–mineral surfaces. It may be reasonable to assume that all soil enzymes remain adsorbed and are not desorbed into solution. This choice introduces other potential sources of artifacts. Typically, soil is suspended in a solution, model substrate added and the concentration of product monitored or assayed after a suitable reaction period, often after stopping the reaction and separating phases by centrifugation. A well-known, but sometimes overlooked example of this is the adsorption of phosphate, the product of phosphatase and phytase reactions. One strategy to circumvent this problem is to estimate the proportion of phosphate product adsorbed from a separate adsorption isotherm and to correct the measured concentration. The use of fluorescent substrate-product pairs has enabled methodological advances, notably with the improvement of detection limits. However, if the reaction product is assayed without separation of the solution and solid phases, there may be artifacts due to absorbance of the fluorescence of the product. Another crucial choice is the composition of the solution used as a background. When solutions are buffered, often to the supposed optimal pH of the enzyme, the dominant cation is often sodium (Na), whereas in soil, calcium (Ca) is more often the dominant cation in both solution and the exchange complex. The catalytic activity of some enzymes requires the presence of calcium to form cation bridges. Ionic strength may also influence catalytic activity. However the major influence is pH. Since there is often a bell-shaped relation between catalytic activity and pH, rather small differences in pH around the optimal pH may have a large effect on measured activity. More importantly, there may be a continuum of pH optima of soil enzymes and this information will not be available from measurement at a single value of pH. Some studies prefer to measure catalytic activity in unbuffered soil suspension, but the pH of such suspensions is liable to be unstable, and pH may vary with the soil:solution ratio of the suspension.

Despite the poor yield of protein desorption, and the absence of a reliable prediction of the bias in desorption and the risk of protein denaturation by chemical extraction conditions, some studies attempt to desorb proteins prior to activity measurements (Tabatabai and Fu, 1992; Fornasier et al., 2015). Although it is well-known that salt solutions have very poor yields in protein extraction, simple salt solutions may be used to avoid protein denaturation. These approaches may avoid some of the experimental artifacts of direct measurement of catalytic activity, such as adsorption of the product, but others remain, including the relevance of model substrates and choice of pH.

Yet another approach to elucidate the interactions of enzymes with soil components and the consequences on enzyme activity and persistence, is to add controlled amounts of model enzymes to soil, or model soil components. The limit to this approach is that both enzymes and substrates are model molecules, often chosen because they are commercially available, not because of their relevance to soil conditions. It has been suggested that extracellular soil enzymes are better adapted to the presence of soil mineral surfaces than enzymes that are not native to soil. Therefore extracellular enzymes of native soils may be more likely to retain catalytic activity following adsorption.

Conformational changes following adsorption are inferred from changes in activity. This is an approximation. Observed activity may result from an average of various conformations, or even of various orientations, some of which may make the active site inaccessible. Decreases of activity with time may be interpreted as the microbial breakdown of enzymes by proteases, but may be due to changes in conformation.

Despite limitations to the interpretation of the study of controlled adsorption of enzymes to soils and soil components, important conclusions have been made. Adsorption is variable, depending on both the enzyme, the surface and external conditions. It is also strongly pH-dependent, and activity is generally observed to be reduced after adsorption. The reduction varies both with the enzyme and the surface, and varies with pH. Asymmetric reduction in activity may lead to a shift in the pH optimum of activity of the adsorbed enzyme, often toward alkaline pH. Every combination of pH-dependence of adsorption and resulting changes in activity have been reported from no adsorption to complete adsorption, and the subsequent reduction in activity being complete, pH-dependent or negligible (Quiquampoix and Burns, 2007). There are rare cases where activation of activity in the adsorbed state have been observed (Allison, 2006). Various explanations of such enhancement of activation include changes in oligomerization, conformation forced by surface shape, such as curved surfaces of nanoparticles, or by the adsorption of inhibitors, allowing a fuller potential of catalytic activity to be expressed.

Soil catalytic activity has been studied as an indicator of soil quality for many decades (Dick, 1994). Originally this arose from the assumption that soil enzymes were of biological origin and thus their presence and thus activity indicated good soil biological health. Usually a combination of different catalytic activities is measured to construct a compound index, avoiding too much emphasis on a single enzyme. Nevertheless, all the above criticisms of soil catalytic activity can be levelled against the quest for a universal index of soil quality.

Glomalin-related soil protein (GRSP)

One protein, or group of proteins, that has received much attention since its first description in 1996 is glomalin, or glomalin-related soil protein (GRSP) (Wright and Upadhyaya, 1996). Although the number of publications and citations

concerning GRSP has increased continuously, this fraction is highly controversial. This is an operationally defined fraction of soil organic matter, initially assumed to be a protein of arbuscular mycorrhizal fungal origin, obtained by the autoclaving of soil in citrate solution. This technique had been used to extract protein from fungal hyphae, and was transposed to soil. It was assumed that other soil proteins did not withstand the harsh extraction procedure. By extension, this fraction is thought to be particularly stable in soil. It is now understood that humic substances and other complex polyphenolic components are co-extracted with soil protein, and that the proteins are not exclusively of fungal origin. A few reports have proposed GRSP as a measure of soil protein in general, however there is no foundation for this assumption. An alternative terminology, autoclaved- citrate-extractible (ACE) protein has been suggested to avoid the assumption of fungal origin, but is not widely used.

Two extraction techniques are used: either a single extraction in neutral (pH 7) 20 mM sodium citrate solution to give easily extractable GRSP, GRSP_{EE}, or repeated extractions in alkaline (pH 8) 50 mM sodium citrate solution to give total GRSP, GRSP_T. It was recommended that the total extraction should be repeated up to 8 times, or until a characteristic reddish-brown color, thought to be the protein, was no longer visible. However there is no independent evidence that the color is caused by protein, since humic substances are known to be co-extracted. After extraction, the protein is usually quantified by the non-specific colorimetric assay known as the Bradford assay, and calibrated by a model protein, bovine serum albumin (BSA). Because of the use of the Bradford assay, some authors recommend the use of the term Bradford-reactive soil protein (BRSP), however this terminology underestimates the importance of the extraction process. This assay is convenient and commercial kits are available, but it has several shortcomings. First, it is non-specific and is subject to both negative and positive interferences, including sample color – authors rarely report any attempt to correct for color. Second, it has a rather small working range and so samples often require dilution. Furthermore, the spectral overlap between the absorbances of the reagent and the reactive product formed between protein and reagent make the calibration curve non-linear. Finally, although BSA is often used to calibrate protein assays; the sensitivity of any assay depends on the amino-acid composition of the protein and on the exposure of the amino acids to the reagents, thus the protein's tertiary structure. The data should therefore be expressed as equivalent BSA and not absolute protein content. One unusual consequence of these artifacts is that the amount of GRSP calculated in a soil extract often appears to depend on dilution. Various solutions have been suggested, including controlled dilution to a target sample absorbance (color intensity), the use of a modified Lowry method in place of the Bradford assay, controlled addition of a protein (BSA) to take account of sample matrix effects, or purification. Attempts have been made to purify the GRSP extract prior to quantification and characterization. Purification often consists of acid precipitation followed by re-solubilization and sometimes dialysis. However, the 'purified' extract usually does not have a typical protein composition: reported C and N contents are unrealistic, indicating that humic-like components are still present. The failure (often unreported) of other approaches to purify these extracts, for example by gel separation or chromatography, suggests that stable bonds have been formed between proteins and other components during the autoclave extraction. An alternative approach to quantification is to use an ELISA (enzyme linked immunosorbent assay) assay. However these assays are not commercially available and so must be developed by each laboratory. The antibody used for these tests, MAb 32B11, was selected because it was found to react against fungal proteins from various hyphae. Immuno-reactive soil protein (IRSP) is generally found to be considerably less abundant than Bradford reactive protein, indicating that non-fungal proteins are extracted, or that the protein is modified by extraction.

Despite the controversy surrounding the nature and origin of GRSP, it is widely studied. It is a minor but significant component of SOM with a possible role in C sequestration. Agricultural soils typically contain a few g kg⁻¹ GRSP, accounting for about 1–5% of SOC, depending on the supposed C content of GRSP. Forest soils, particularly tropical forest soils, have larger GRSP contents. The GRSP increases with increasing SOC, leading to doubts that it is a distinct fraction of SOM. Similarly it is positively correlated with soil nitrogen, which is consistent with the large N content of proteins (around 16%). When changes in land use lead to declines in SOM, GRSP often shows better resistance, leading to an enrichment of SOM in GRSP (Preger et al., 2007; Cissé et al., 2020). This observation has reinforced the hypothesis that GRSP is a stable fraction of SOM. An alternative hypothesis is that GRSP input to soil depends on plant cover (Cissé et al., 2021). The ratio GRSP:SOC tends to be largest under intensively farmed cereal crops and smallest in organic-rich forest soils (Staunton et al., 2020). A study of archived soils from long-term bare fallow soils showed that both GRSP and SOM declined with time over a period of decades; the decline in GRSP was not always slower than that of SOM.

The GRSP is widely considered to be a convenient, low-cost marker of fungal activity and turnover. However weak and inconsistent correlations are often found between various GRSP contents (EE and T, Bradford reactive and immune-reactive) and other fungal markers. This may be due in part to differences in turnover times and persistence of fungal hyphae and proteins in soil, but also reflects the reality that GRSP is not exclusively of fungal origin.

Glomalin-related soil protein (GRSP) is assumed to confer physical stability to soils and this is supported by the correlations observed between GRSP content and physical stability (Rillig et al., 2002). However in the majority of these studies, the possible relation between SOC and GRSP is untested, therefore begging the question as to the specific role of GRSP. The same criticism may be levelled against the affirmation that GRSP sequesters metals in soils and sediments. Originally the link between GRSP and metal (contamination) arose from the assumptions that GRSP is a marker of fungal activity and that fungal activity will be negatively impacted by metal contamination (Cornejo et al., 2008). This was generally deduced from the metal content of extracted GRSP, however when metal contents of GRSP and SOM are compared, the capacity of GRSP to sequester metals is not conclusive.

Glomalin-related soil protein (GRSP) is thought to be a stable fraction of SOM, with an average age estimated as being years to decades. This age is considerably longer than that of fungal hyphae, but in accord with SOM age, although this is often cited as evidence of the recalcitrance of GRSP in soil. Small seasonal variations of GRSP have been reported by some studies (Gispert et al., 2018), and this tends to contradict the assumption of recalcitrance of GRSP. The GRSP_{EE} is often assumed to be more recent than the

total fraction. The underlying logic to this assumption has not been explicitly described nor has the hypothesis been independently tested. One explanation would be that with time proteins become increasingly strongly bound to soil, a process known as fixation, and thus more difficult to remove. However this has never been tested for GRSP and rarely for other proteins at appropriate time scales. The often reported strong correlation between the two fractions contradicts a marked difference in age.

Potentially hazardous proteins in soil: Prions and Bt (*Bacillus thuringiensis*) proteins

Two groups of proteins potentially present in soil have attracted concern since the late 20th century. Prion proteins are the infectious agents responsible for transmissible spongiform encephalopathies (TSEs), or prion diseases (Saunders et al., 2008; Smith et al., 2011). One of these diseases, scrapie, has been known to affect sheep for centuries, and the role of soil as a reservoir has been suspected for decades. However it was the cross species transmission with the appearance of bovine spongiform encephalitis, BSE (mad cow disease) and a new variant of Creutzfeldt-Jakob disease in humans, linked to the use of contaminated meat and bone meal as animal feed that sparked interest in the role of soil in the transmission of these diseases. The current research focus has moved from Europe to North America where wild deer (cervids) suffer from chronic wasting disease (CWD). Prion proteins enter soil from contaminated carcasses, animal excreta and inadequately inactivated meat and bone meal. They may pass from soil to animals by soil ingestion. They are known to conserve biological properties after adsorption on soils, and possibly for years. This implies that the proteins conserve their conformation after adsorption, and that adsorption protects them against microbial and protease breakdown. It appears that prion proteins may be biologically active and cross biological membranes while remaining in the adsorbed state. Pathogenicity is assessed using bioassays, however these require large numbers of sensitive animals, and so are time consuming, expensive and variable. Most studies therefore prefer assays of soluble protein, thus requiring prior extraction of the proteins. On the basis of the few available studies, the infectivity appears to decline more slowly with time than does chemical extractability. No universal extraction technique exists, but as for other proteins, high pH, large salt concentration, detergents and the addition of an indifferent protein improve the extraction yield. Quantification methods for the soluble protein are usually ELISA tests, with many commercially available kits. An interesting alternative to extraction-detection is protein misfolding cyclic amplification (PMCA) that appears to give good detection efficiency.

Another group of proteins of environmental concern are known as Cry or Bt proteins. They have insecticidal properties and are introduced into soil by the endemic bacterium *Bacillus thuringiensis* or by a class of genetically modified (GM) (Spohn et al., 2016) crops, known as Bt-crops, that have been engineered to produce one or more of the proteins. The insecticidal properties of these proteins results from a complex series of reactions involving protein oligomerization and attachment to specific receptors in insect guts (Clark et al., 2005; Helassa et al., 2013). There is no known mechanism for these proteins to affect mammals adversely, but their persistence in soil has other important implications. These include the possible exposure to non target insects, the low-level exposure to target insects that would accelerate the appearance of resistance and soil monitoring for the surveillance of GM use or for organic farming certification. A very large number of proteins are known to be produced by *B. thuringiensis*, although only a small number have been characterized. The bacterium produces large amounts of protein, up to 30% of its mass during sporulation. It is the crystal-like appearance of the proteins at this stage that has caused the name Cry to be given to them. Each strain produces a small number of proteins, usually between 1 and 5, and the proteins have a very narrow, highly specific range of target insects that must ingest the protein to be exposed to its toxic properties. Toxins and spores are widely used as biopesticides. A very small number of proteins is produced by GM crops, and the protein they synthesize may enter soil by root exudation, or the decomposition of crop residues. An important difference between the proteins produced by the bacterium and those produced by GM crops, is that the former are protoxins, with molecular masses of about 73–130 kDa. The first step in the process of toxicity is the enzymatic cleavage of these protoxins in the alkaline mid-gut of insects, whereas GM plants synthesize the toxin directly, with a molecular mass of about 60 kDa.

All Cry proteins are strongly adsorbed on soil organo-mineral surfaces. Adsorption isotherms conform to the Freundlich isotherm, with maxima in accord with the specific surface area of the mineral. However, at lower concentrations there is no consensus on a relation between affinity and the nature of the mineral surface. In solution, many have a strong tendency to oligomerize, and thus must be stored at high pH in concentrated salt solutions. These properties complicate the experimental investigation of their properties and adsorption behavior, and can lead to artifacts and incorrect interpretation of observations. It is probable that monomers and oligomers have different adsorption properties, and there is spectroscopic evidence from FTIR that oligomerization is impeded after adsorption (Helassa et al., 2011). There are conflicting data on the persistence of Cry proteins in soil, with some studies reporting the rapid disappearance of the protein, and others claim it can be detected for months. The cause of these discrepancies may lie in the difficulty of chemical extraction of the protein prior to quantification. As for other proteins, extraction is promoted by large pH, high salt concentration, the addition of detergent and another protein. The insecticidal properties can be monitored using a large, relatively easily manipulated insect, *Manduca sexta*. The insecticidal properties are conserved after adsorption, which may appear surprising since the mechanism of toxicity requires the proteins to be in solution. However, the composition of the insect mid-gut resembles that of many efficient extraction solutions; high pH and presence of surfactants. Toxicity of soil-adsorbed Cry protein, measured with *Manduca sexta* bioassays, and quantification using commercial ELISA kits following chemical extraction, follow the same trends. The temperature effects of the decline in toxicity and extractability suggest that declining toxicity may be explained by time-dependent fixation of the protein on mineral surfaces, rather than microbial breakdown (Hung et al., 2016).

Soil metaproteomics

Metaproteomics is the large-scale characterization of the entire protein complement of an ecosystem. This is made feasible by large throughput technology. The term is a parallel to meta-genomics, the term coined in the early 21st century as an alternative to microbial environmental genomics, to avoid the bias toward culturable bacteria (Rodríguez-Valera, 2004). The underlying driver for such research is that improving knowledge of a system must lead to progress, even if the precise nature of the progress is not fully predictable. Meta proteomics of many environmental systems has made remarkable progress. There are three steps in such analysis: extraction; purification; analysis by mass spectrometry. There was a flurry of enthusiasm for soil metaproteomics, but this has petered out (Bastida et al., 2009; Keiblinger et al., 2012). There are two major reasons for this. The greatest barrier to any systematic study of extracellular soil proteins is the absence of a robust method to extract and purify proteins efficiently and without bias. As has been discussed in the previous section, proteins are intrinsically difficult to desorb from surfaces. The situation in soils is further complicated by the diversity of organo–mineral surfaces in soils and of extracellular proteins. To date there is no widely accepted method to extract proteins from soils. As has been described above, detergents, alkaline pH, large salt concentration and indifferent proteins have been found to be effective to extract some proteins, but there have been no systematic studies. Furthermore extracted proteins must be separated from the extractant that contains detergent, for example, and co-extracted organic compounds (see the example of GRSP above) before analysis. It has proved difficult to separate protein from other soluble soil organic components. The contamination of extracts with tannin and various humic-like components preclude the use of separation by gel electrophoresis. In the few published studies of soil proteome, the number of proteins identified by gel electrophoresis is astonishingly small; tens or hundreds. Finally, the identification of proteins and their attribution to soil biota will be limited by the paucity of knowledge of soil biota. The study of proteins associated with soil biota, namely intracellular proteins, has been somewhat more successful. By first removing free-living biota from soil, the extraction process is simpler, and less subject to subsequent interference in the quantification and characterization of proteins (Maron et al., 2007). Soil metaproteomics is an exciting field of research that requires a technological leap to allow significant progress in the future.

Conclusions

The chemistry of proteins has important consequences on their role and dynamics in soil. Interpretation of the quantification of proteins and measurements of their persistence and reactions may be erroneous if essential features of their chemistry are overlooked.

Abstract

Biochar is a carbon-rich solid made by the pyrolysis of organic wastes and other feedstocks for soil and other environmental applications. Its chemical and physical properties are highly variable, depending strongly on the feedstock, pyrolysis temperature and conditions used for its production. This chapter reviews important chemical and physical properties of biochars arising from particular types of feedstock and pyrolysis temperatures. It reviews the effects of additions of biochar on the chemical, physical and microbial properties of soil, and on crop yields. It includes novel applications for the remediation of contaminated soil and its use in complex fertilizers. Last, it identifies topics for future research.

Key points

- Biochars are made from various feedstocks and under various pyrolysis conditions.
- Biochar added to soil, has important effects on properties and can increase crop yields.
- Novel uses of biochar are its addition to fertilizers and for remediation of contaminated soil.
- Further research on use of biochar in agriculture is suggested.

Introduction

Biochar is a stable solid material, rich in carbon (C), produced by thermal decomposition of organic material in the absence of oxygen or with too little oxygen for combustion. It has a predominant condensed-aromatic structure that makes it chemically and biologically persistent and able to remain in soil for several decades and even for millennia. When added to soil, it remains as a long-term store of C, and it improves soil conditions for plant growth. The idea of adding biochar to soil arose from observations made on the Amazonian dark earths ('Terra Preta do Indio' of Brazil), which contain more stable organic C than the surrounding soil and are more productive (Glaser, 2007). Natural wildfires also produce charred material and soot which are commonly referred to as either black carbon or pyrogenic C. According to Reisser et al. (2016) pyrogenic C constitutes on average 13.7% of the soil's organic C globally and as much as 60% in some places.

In the 1990s, scientists saw the deliberate conversion of waste biomass into biochar and its addition to the soil as a means of storing C and mitigating global warming; the soil could serve as a carbon sink. Lehmann et al. (2021) estimated that application of biochar to the soil could diminish emissions of greenhouse gases and remove CO₂ by 3.4 to 6.3 Pg CO₂ equivalent per year: a significant effect. Biochar can also help to preserve organic matter in the soil through negative priming. Addition of biochar to soil

improves the soil's physical, chemical and biological properties associated with plant nutrition thereby leading to enhanced growth and larger yields of crops. These benefits can vary significantly, depending on the feedstock used for biochar, the pyrolysis temperature, and on the soil and its environment. Here, we review the properties of biochar, the effects of biochar on the soil's chemical, physical and microbial properties and implications for agronomy and the environment. The research on biochar done in the last 20 years has resulted in a huge literature recording the results, some of which conflict. We cite only a small proportion of the sources but have attempted to list the most significant and informative.

Properties of biochar

Production

The properties of biochar vary, depending on the conditions of pyrolysis and on the feedstock and other ways in which it is treated, including hydrothermal carbonization, gasification, and flash carbonization. Pyrolysis is a thermochemical decomposition of biomass under anoxic conditions at temperatures ranging from 350 °C to 800 °C or more; it is the commonest means of biochar production. The product is a solid material, biochar, plus liquid tar and a mixture of gases including H₂ (hydrogen), CH₄ (methane), CO₂ (carbon dioxide) and CO (carbon monoxide). The relative yields of these products vary depending on the nature of the biomass, the temperature and the rate of heating. Increases in temperature and residence time reduce the yields of biochar. Low temperatures lead to greater production of liquids, whereas at high temperatures more gases are produced. Increases in temperature also lead to a decrease in acidic functional groups and an increase in the salts of alkali and alkaline earth elements in the biochar.

As the temperature increases there is a progressive loss of oxygen (O) and hydrogen (H), both of which are lost rapidly between 300 °C and 500 °C. The organic compounds in the feedstock, such as cellulose, hemicellulose, and lignin, decompose through the cleavage and cracking of weak bonds, and condensed aromatic structures are generated during heating. The main sources of feedstock are biological wastes: wood, crop residues, weed grass, and manure. Characteristics of biochars produced from different feedstocks differ somewhat from one another and are described below.

Soluble salts, ash, pH, and liming potential

Biochars contain readily soluble salts, in particular chlorides of potassium (K), sodium (Na) and calcium (Ca), carbonates, and bicarbonates of Ca, Na, and magnesium (Mg), and sulfates and phosphates of Ca, K, and Mg. These salts contribute to the alkalinity of biochars, although the particular mixtures of the salts depend on the feedstock and production process. They confer a pH on the biochar that is generally neutral to alkaline, consequently giving it a value for liming.

Biochars made from woody biomass (median pH 8.1) are generally less alkaline than those made from grasses (median pH 9.0), crop residues (median pH 9.3) and manures (median pH 9.4) (Fig. 1). Exceptions to this are biochars from some species of trees, in particular of pine (*Pinus*), eucalyptus (*Eucalyptus*) and oak (*Quercus* L.), produced at low temperatures (≤ 350 °C), which can have

Fig. 1 Distributions of pH of biochars: (A) box-plots for four feedstocks; (B) individual values classified by pyrolysis temperature and feedstock. The number of observations for woody biomass, crop waste, grass and manure biochars is 74, 8, 40 and 78, respectively. In Fig. 1A the red and black lines indicate median and mean values, respectively while the circles in the boxplot indicate outliers. Data were taken from Campos et al. (2020); Domingues et al. (2017); Enders et al. (2012), Mukherjee et al. (2011) and Novak et al. (2009) cited in Singh et al. (2017); Kloss et al. (2012), Rajkovich et al. (2012) and Zhao et al. (2013) cited in Ippolito et al. (2020); Singh et al. (2010); and Zhang et al. (2017).

pH < 5. The pH of biochar generally increases with increasing temperature of the pyrolysis from 350 °C to 550 °C with a maximum of about pH 10. Further increases in temperature tend to lead to small decreases in pH (Fig. 1B).

It is the ash in biochar that can make it alkaline and hence effective as a liming agent, particularly on acid soils. Biochar's liming potential is measured as CaCO_3 equivalent, which is closely related to its ash content, and is greater in biochars made from manures, grasses, and crop wastes than from the woody biomass biochars (Fig. 3). The combination of plant nutrients and base cations in the ash make biochar valuable as both a fertilizer and a counter to the soil's acidity. In general, the richer are biochars in plant nutrients, the greater are crop yields resulting from their application.

The presence of salts in biochars often increases electrical conductivity (EC) of soils, and the increase in EC depends to some extent on the feedstock and pyrolysis temperature (Fig. 2), and the rate of biochar application to soil. Biochars from wood and grass have median ECs of 0.24 and 0.30 dS m^{-1} , respectively, whereas the median EC of biochar from crop residues is 0.57 dS m^{-1} but for biochar from manure it is much larger at 4.33 dS m^{-1} . The EC tends to increase with increasing pyrolysis temperature to between 500 °C and 600 °C, which is attributed to an increase in the residual ash during pyrolysis. Biochars produced at low temperatures from nutrient-rich feedstocks can still have large ECs, however, because de-protonated volatile molecules and small organic molecules are present.

Salts are part of the ash in biochars, which also tend to increase with increases in the temperature of pyrolysis, to a maximum about 600 °C, and with the duration of heating (Fig. 3). The composition of the ash also varies widely with differences in feedstock. In general, the richer is the feedstock in mineral elements, the more ash there is in the biochar. Fig. 3 shows the proportions of ash in biochar from grass (median 14.6%) to be the largest and that from woody biomass biochars (median 2.4%) to be least. We do not have precise estimates of the liming value of the ash, but we can expect that biochars from wood are likely to be less effective than those produced from the other three feedstocks (Fig. 3C and D). Nevertheless, strongly alkaline biochar is valuable for ameliorating acid soils.

Total carbon, nitrogen, oxygen, and hydrogen

The content of total C in biochar is important. It varies considerably from one feedstock to another. It is the greatest in wood biochars (mean 77.8%) and the smallest in biochars from manure (mean 62.1%) (Table 1). The proportions of C in biochars made from grass (mean 64.2%) and crop wastes (67.7%) are only slightly larger. For biochars that contain carbonates the total C concentration should be taken into account when the proportions of organic C are estimated. The proportions of nitrogen (N) in biochars rank in reverse order to those of C; the largest are in manure biochars and smallest in wood biochars (Table 1). The concentrations of O and H are much the same for all feedstocks, but both decrease with increasing temperature of pyrolysis as O- and H-containing compounds, such as ethers and lactones and the functional groups hydroxyl, carboxyl carbonyl, are lost. So too are the easily decomposable substances and volatile compounds containing N and S. In particular, the atomic ratios H/C_{org} and O/C_{org} decrease as the pyrolysis temperature increases. The net result is increased concentration of other major elements C, Ca, Mg, and K.

The nutrients P, K, Ca, and Mg and the trace elements copper (Cu), zinc (Zn), manganese (Mn) and iron (Fe) are generally most concentrated in manure biochars and are least in wood biochars (Table 2). The concentrations of most nutrient elements are closely related to the proportions of ash in the biochars.

Fig. 2 Distributions of ash and CaCO_3 equivalent (liming value) of biochars: (A) box-plots of ash for four feedstocks; (B) individual values of ash classified by pyrolysis temperature and feedstock. (C) box-plots of CaCO_3 equivalent of biochars for four feedstocks; (D) individual values of CaCO_3 equivalent classified by pyrolysis temperature and feedstock. The number of observations for woody biomass, crop waste, grass and manure biochars is 68, 6, 36, and 72, respectively for ash content while these values are 10, 2, 8, and 16, respectively for the liming value. The red and black lines indicate median and mean values, respectively while the circles in the boxplot indicate outliers. Data sources are the same as given in Fig. 1.

Fig. 3 Distributions of electrical conductivity (EC) of biochars: (A) box-plots for four feedstocks; (B) individual values classified by pyrolysis temperature and feedstock. The number of observations for woody biomass, crop waste, grass and manure biochars is 47, 2, 18, and 56, respectively. The red and black lines indicate median and mean values, respectively while the circles in the boxplot indicate outliers. Data sources are the same as given in Fig. 1.

Surface charge characteristics of biochars

Surface charge on biochar particles is generated mainly by the de-protonation of hydroxyl, carboxylic, lactonic and phenolic functional groups. These groups differ in their pK_a values; those for most carboxylic groups fall between 2 and 4, those for lactonic groups between 4 and 7, and for phenolic groups from 7 to 10 and more. Within the normal range of pH for most agricultural soil, carboxylic and lactonic groups of biochar predominantly de-protonate and thereby contribute to the cation exchange capacity (CEC). Given that native soil organic matter has larger CECs (average $280 \text{ cmol}_c \text{ kg}^{-1}\text{C}$) at pH 7 than fresh biochar (usually $<100 \text{ cmol}_c \text{ kg}^{-1}\text{C}$), the latter only contributes significantly to the soil's CEC in the short-term in soils with a small CEC, such as sandy soils and those poor in organic matter. Over time, however, biochar is oxidized, and functional groups of C form on biochar surfaces and increase the CEC of most soils. Such data as we have suggest that CECs are broadly similar for biochars made from different feedstocks and at different pyrolysis temperatures (Fig. 4): median CECs are $9.7 \text{ cmol}_c \text{ kg}^{-1}$ for biomass from wood and crop residues, $9.8 \text{ cmol}_c \text{ kg}^{-1}$ from grass, and $10.7 \text{ cmol}_c \text{ kg}^{-1}$ from manures. No clear relationship between CEC and pyrolysis temperature is evident, although we might expect that cleavage and loss of acidic functional groups caused by increasing temperature would result in a decrease in CEC.

Fresh biochars have some anion exchange capacity (AEC), but this is generally smaller than their CEC, and it decreases rapidly over time. Singh et al. (2010) analyzed 10 biochars made from various feedstocks and found values of AEC ranging from 31 to $1030 \text{ cmol}_c \text{ kg}^{-1}\text{C}$, with generally smaller values for wood biochars and larger ones for biochars made from paper sludge and manure.

Bulk density, pore space, and specific surface area

Biochars are generally highly porous, particularly those produced from grasses and woody materials. Feedstock type, pyrolysis conditions and/or pre- and post-pyrolysis processing influence the particle size, density, porosity, and hydrophobic or hydrophilic properties of biochars. Fig. 5 summarizes the bulk density, pore volume, and specific surface area of biochars produced from the principal feedstocks. Biochars from grass and wood have median bulk densities $<0.2 \text{ g cm}^{-3}$, while the medians for crop waste and manure biochars are 0.23 and 0.39 g cm^{-3} , respectively. Pore volume is greatest in woody biochars (median 57.2%) with much smaller values for manure biochars (median 4.9%) and even smaller values for grasses and crop waste biochars (median 1.1% and 0.04% , respectively). The specific surface area of woody biochars is the greatest (median $108.3 \text{ m}^2 \text{ g}^{-1}$), followed by manure (median $45.0 \text{ m}^2 \text{ g}^{-1}$), and crop waste (median $28.1 \text{ m}^2 \text{ g}^{-1}$) biochars, and the minimum is for grass biochars (median $8.7 \text{ m}^2 \text{ g}^{-1}$). There is no consistent trend in physical properties with pyrolysis temperature for different feedstock biochars.

Chia et al. (2015) showed that micropores contribute significantly to the surface area of biochars. Based on the data from several published studies, they showed a linear relation between the micropore volume and BET (Brunauer–Emmett–Teller) surface area of many biochars. They found that both the micropore volume and BET surface area were much greater for activated biochar (range 0.056 to $0.72 \text{ cm}^3 \text{ g}^{-1}$ and 156 to $2436 \text{ cm}^3 \text{ g}^{-1}$, respectively, whereas the corresponding values for non-activated biochars were 0.002 – $0.2 \text{ cm}^3 \text{ g}^{-1}$ and 4 – $448 \text{ cm}^3 \text{ g}^{-1}$).

Fig. 4 Distributions of cation exchange capacity (CEC) of biochars: (A) box-plots for four feedstocks; (B) individual values classified by pyrolysis temperature and feedstock. The number of observations for woody biomass, crop waste, grass, and manure biochars is 20, 18, 4, and 22, respectively. The red and black lines indicate median and mean values, respectively while the circles in the boxplot indicate outliers. Data were taken from Ippolito et al. (2020); Souza et al. (2021) and Zama et al. (2017).

Biochar applications

Biochar for long-term carbon storage in the soil

Biochar remains in the soil for much longer than uncharred biomass; that is its advantage for C retention. To maximize that advantage for soil acting as a C sink, the biochar production system should be tuned so that the output contains large concentrations of C (Table 1) with large and condensed aromatic moieties or structures, while minimizing the C used to collect, transport and store the feedstock, in the pyrolysis, post-processing, and during application to the land.

To maintain that advantage, biochar must be produced only from organic wastes such as crop residues and prunings or from trees grown in short rotation for the purpose. In the latter case the next generation of trees has the further advantage of capturing C from the atmosphere. This advantage can be expressed as carbon debt (Lehmann et al., 2021); that is the difference in the amount of CO₂ released through pyrolysis and that released during the decomposition of the same amount of un-pyrolyzed feedstock. It needs to be small. Most crop residues have a small C debt; purpose-grown trees tend to have a larger debt. In the latter situation planners must show that there is or will be a net reduction in the amount of C lost to the atmosphere over the life-cycle of a rotation and thereby reduce the damage to the environment.

Biochar contributes to the labile fraction of C in soil, especially if produced at low temperature. This fraction together with plant nutrients and alkalinity can stimulate microbial activity and trigger the mineralization of native soil organic matter in the short term. This is also referred to as positive priming. The increase in alkalinity might also weaken the bonds of organic ligands to mineral surfaces, and thereby increase the labile pool of C. In the long term, however, biochar has a net negative priming effect because its surfaces provide new sites on which organic ligands can be preserved. The overall effect is to sequester C and reduce the amount of CO₂ released into the atmosphere (Lehmann et al., 2021).

The overall CO₂ removal created by biochar production relies heavily on the C sink potential of the biochar. The rate of degradation of the biochar C must be several orders of magnitude slower than that of un-pyrolyzed feedstock C when that is left to decompose naturally. The 'Stable C Protocol' was developed by the International Biochar Initiative (Budai et al., 2013) and is based on the relation between the H/C_{org} ratio of biochars and their rates of degradation determined in incubation experiments with biochar in soil of 3–5 years duration. The methodology has been further refined first by Lehmann et al. (2015) and, recently, by Woolf et al. (2021) by the provision of a regression equation as shown in Fig. 6, which provides estimates of the fraction of organic C (C_{org}) in biochar, referred to as F_{perm}, that will remain in the soil for more than 100 years at a soil temperature of 14.9 °C (the mean annual air temperature in croplands globally). The equation is—

Here H/C_{org} is the molar ratio of H and C in organic forms. The choice of 100 years arises from the time frame used by the Intergovernmental Panel on Climate Change (IPCC) for assessing the potential of greenhouse gases to warm the planet (IPCC, 2007). The authors also provided permanence coefficients for biochar C sequestration as a function of other soil temperatures (ranging from 5 °C to 25 °C) for different time frames (100–1000 years).

The atomic H/C_{org} and therefore F_{perm} are strongly associated with the degree of aromatic condensation of C in biochar. The IPCC (2019) has recently proposed a method of assessment that would allow biochar to be included in national inventories as a soil

Fig. 6 Relationship between F_{perm} (the fraction of biochar carbon remaining in soil after 100 years) and the molar ratio of hydrogen to organic carbon (H/C_{org}) in biochar. Biochar pyrolysis temperatures below 350 °C were excluded in the data. In all cases, F_{perm} values were calculated for a soil temperature of 14.9 °C (the mean annual air temperature in croplands globally). The dashed lines indicate 95% confidence intervals. From Woolf, D, Lehmann, J, Ogle, S, Kishimoto-Mo, AW, McConkey, B, and Baldock, J (2021). Greenhouse gas inventory model for biochar Additions to soil. *Environmental Science & Technology* 55(21):14795–14805.

amendment. It would use predicted values of F_{perm} (also referred to as BC_{+100}) based on the pyrolysis temperature, because that information is more readily available than the $\text{H}/\text{C}_{\text{org}}$ ratio.

Fertilizer benefits of biochar in soil

The concentration of nutrient elements in a feedstock is the single most important factor governing the potential fertilizer value of a biochar. Those concentrations vary widely, and not all biochars have value as fertilizer. The International Biochar Initiative (IBI) has set certification standards for the fertilizer values of biochars; five classes are recognized, based on their total and available concentrations of P (phosphorus), K (potassium), S (sulfur) and Mg (magnesium). Biochars made from wood generally have the smallest nutrient concentrations, and those from manures (and food wastes) have the largest. Nutrient concentrations in biochars from crop residues and grasses are intermediate (Table 2). The proportion of N (nitrogen) retained from the original feedstock depends on the temperature of the pyrolysis; for example, Lang et al. (2005) found that the proportion in biochar from three woody and four herbaceous feedstocks started to decline at about 400 °C, and nearly half of the N was lost at about 750 °C. Other investigators have reported similar effects, in particular for manures. The N available for plant nutrition also declines with the increase in pyrolysis temperature because aromatic and heterocyclic N–ring structures are formed, and these are slow to disintegrate in the soil. Phosphorus, in contrast, has been found to increase in proportion as the temperature of the pyrolysis increases to 600 °C, but it can decrease at higher temperatures.

The available P (i.e., that extracted in 2% formic acid) of biochars, rich in ash, ranges between 26 and 93% of the total P content, and this value largely depends on the type of feedstock and pyrolysis temperature (Wang et al., 2012). The concentration of total K has been found to increase from 3.7% at 300 °C to 5.0% at 600 °C, and that which is available (i.e., water-soluble K) to increase from 37% to 47% of the total K (Zheng et al., 2013). Other major nutrients, namely S, Ca, and Mg also remain in the ash fraction, and the amounts therefore depend on the type of feedstock (Table 2). The proportion of extractable S has been found to increase from 10 to 76% with an increase in temperature, and 35% to 100% of the Ca and 18% to 95% of the Mg are readily soluble.

Influence of biochar on soil physical properties

Addition of biochar to soil can change the soil's pore-size distribution, water-holding capacity, hydraulic conductivity and total porosity (and so decrease the bulk density). The extent of the changes depends on the properties of the biochar (including its particle-size distribution) and of the soil. Decreases in bulk density of 7.6% to 12.0% on average have been reported (Table 3), the largest being for fine-textured soil, and less for medium- and coarse-textured soil. Recently, Blanco-Canqui (2017) found the

Table 3 The effects of biochar application on important soil physical properties.

<i>Soil property</i>	<i>Biochar's effect on soil property</i>	<i>Number of studies</i>	<i>References</i>
Bulk density	Decreased—		
	3–31%; average = 12%	19	Blanco-Canqui (2017)

	Increased—		
	average = 17.8% in fine textured soils	18	Omondi et al. (2016)
	average = 27.3% in medium textured soils	30	
	average = 36.5% in coarse textured soils	28	
	Increased—		
	4–58%	21	Blanco-Canqui (2017)
	1.1–15.7%; average = 8.2%	10	(Omondi et al., 2016)

opposite trend, however, with the addition of biochar increasing the porosity of coarse-textured soil most. The effect was attributed to several factors, in particular increased interaction with mineral particles favoring their aggregation and resistance to packing.

Results from both field and laboratory suggest that addition of biochar can alleviate compaction in modern agriculture. The increased porosity of the soil enhances the movement of water, heat and gases, though these effects do not necessarily benefit plant growth. The effects on hydraulic conductivity depend strongly on the soil's texture. In particular, they decrease with increasing clay content (Table 3). Blanco-Canqui (2017) reported a decrease in coarse-textured soils, an increase in fine-textured and compacted soil, and no effect on medium-textured soil (Table 3). The variation in response has been explained largely by big differences in the pore-size distribution of both soil and biochar and by biochar particles' filling of the existing pore space. Most studies have shown that biochar increases water retention and available water in soil, with coarse-textured soils being more responsive than fine-textured ones.

Herath et al. (2013) showed that in two silty loam soils the change in soil water availability was quite different with the application of identical types and amounts of biochar. The increase in plant available water was greater in the Alfisol than Andisol with the application of maize stover biochars produced at 350 °C and 550 °C (Fig. 7). The increase in water retention and available water in coarse-textured soil has been attributed to a decrease in the average pore size and an increase in the proportion of micropores and specific surface area. Not all applications of biochar have increased the soil's water retention, however; the hydrophobicity of fresh biochar is the likely reason. As biochar ages in the soil, O-containing surface functional groups form on biochar surfaces so that they become hydrophilic and both infiltration and retention increase. These observations are based mostly on short-term laboratory studies. Long-term studies in the field are needed to confirm the effects, which also depend on the rate of application.

Effects of biochar application to soil on crop yield

Experimental results on the effects on plant production and crop yield published since 2010 report estimated average increases of between 9 and 17% in the yields of field crops (Fig. 8). In most, yield responses have been largest on acidic and sandy soil, on soil

Fig. 7 Matric potentials of soil mixed with maize stover biochar for two soil types: (A) an Alfisol and (B) an Andisol. The plotted symbols are means of measurements on three samples. From Herath, HMSK, Camps-Arbestain, M, Hedley, M, et al. (2013). Effect of biochar on soil physical properties in two contrasting soils: An alfisol and an andisol. *Geoderma* 209–210: 188–197.

Fig. 8 The mean effects of biochar application on plant productivity or crop yield in soils (redrawn after Jeffery et al. (2017); Dai et al. (2020) and Ye et al. (2020)). In the first two studies the effects of biochar application are compared to undefined controls (Jeffery et al., 2017; and Dai et al., 2020), whereas Ye et al. (2020) evaluated (i) the effects of biochar application together with inorganic fertilizer (IF) compared to 'fertilized control' and (ii) the effects of biochar application with and without IF and or organic amendment (OA) relative to the fertilized control. The error bars represent 95% confidence intervals in the three datasets. The number of pair-wise observations for each study are given in the parentheses.

with small CEC and little organic matter, particularly in the tropics. As one might expect, addition of nutrient-rich biochar has enhanced yields more than less rich biochar.

There is a growing interest in the potential benefits of fertilizers augmented with biochar. Ye et al. (2020) showed that biochar in combination with inorganic fertilizers, increased crop yield by 14.5% compared with fertilized controls. The overall increase in yield with biochar (with and without inorganic fertilizer and or organic amendment) relative to the fertilized control was 9.9%. The authors only considered field studies, with application rates $\leq 20 \text{ t ha}^{-1}$, and yield data within first year of application. They found that application rates of $>10 \text{ t ha}^{-1}$ did not contribute to further increases in crop yield.

Combined biochar and inorganic fertilizer (biochar-based fertilizers) can locally increase the CEC around the fertilizer granules, water retention and microbial activity. From a recent meta-analysis, Melo et al. (2022) reported that when C-rich biochars produced at a high pyrolysis temperature were part of these composite fertilizers, plant growth was greater than that achieved with conventional fertilizers. The authors suggested the potential role that this type of biochar may have is as electron shuttle in the rhizosphere that improves nutrient uptake.

Biochar and the soil microbial community

Biochar can profoundly influence the soil's biome. The following are reported to have been increased in soil after the addition of biochar (Zhang et al., 2018), with the mean increase in parentheses: activity of all microorganisms (total phospholipid-derived fatty acids (PLFA), 8.3%), bacteria (20%), fungi (19%), actinomycetes (9.1%), Gram-positive bacteria (11%), and Gram-negative bacteria (13%). These effects of biochar can be attributed directly to a safer habitat, better nutrition, more pore space and more available water. They might also have been brought about less directly by a more favorable pH and greater CEC. Addition of biochar could therefore change the composition and activity of the microbial community, and the soil food web, which might affect the cycling of soil organic matter and major nutrients, and consequently affect plant growth. The interactions of biochars with soil minerals enhance water and nutrient retention, which in turn would increase microbial biomass over time.

Biochar can increase the abundance of bacteria involved in N cycling including denitrifiers and thereby reduce emissions of N_2O from the soil (Borchard et al., 2019). It can increase biological fixation of by promoting the activity of *Rhizobia*, too. These effects depend to some extent on the nature of both the soil and the biochar, and on the rate and method by which the biochar is applied (Borchard et al., 2019). Biochars with liming potential when added to acid soil decrease the exchangeable acidity and concentration of free aluminum. This causes a shift in the soil's microbiome. Biochars produced at low temperature when added to soil containing little organic C ($<1\%$) were found to increase the fungi-to-bacteria ratio by 38%, and this response was larger in acidic soil than in neutral and alkaline soil. Acid conditions favor fungi over bacteria.

Some biochars carry toxic constituents, such as polycyclic aromatic hydrocarbons (PAHs) that can be produced during the thermal carbonization process. Pine biochars produced at low temperature ($\leq 400^\circ\text{C}$) can contain phenolic compounds, such as retene, in their water-extractable fractions. These can harm soil microorganisms or inhibit their growth. In some instances, the total microbial biomass and mycorrhizae decreased after the addition of biochar, seemingly because of nutrient limitations. Increasing the dominance of certain microbial species, following biochar application, can reduce the diversity in the soil's whole microbial community.

Biochar standardization and quality assurance for potential contaminants

Given the diverse qualities of biochar, several agencies, including the IBI, the European Biochar Certificate and the Australia New Zealand Biochar Initiative (ANZBI) have established voluntary standards for the material; they have sought a legislated system of certification (Meyer et al., 2017). This is important because some biochars contain contaminants, either present in the feedstock or formed during the pyrolysis.

Potentially toxic elements (PTE) include cadmium (Cd), copper (Cu), nickel (Ni), chromium (Cr), zinc (Zn), lead (Pb) and arsenic (As). Their concentrations depend primarily on the feedstock, and they can become concentrated during pyrolysis. If their initial concentrations in the feedstocks are small, however, they are unlikely to exceed limits set by the regulatory agencies. Biochars from the redwood (*Sequoia sempervirens* (D. Don) Endl.), rice straw, maize, bamboo, and softwood were found to have the following concentrations (in mg kg^{-1}): As 0.03–0.27, Cd 0.02–0.94, Cr 0.12–6.48, Cu 0.04–13.2, Ni 0.1–1.37, Pb 0.06–3.87, and Zn 0.94–207. The concentrations varied substantially from one feedstock to another; bamboo biochar had the largest concentrations of Ni (1.37 mg kg^{-1}), Pb (3.87 mg kg^{-1}), Zn (207 mg kg^{-1}), and As (0.29 mg kg^{-1}); redwood biochar had the largest concentration of Cd (0.94 mg kg^{-1}); maize biochar had the largest concentrations of Cr (6.48 mg kg^{-1}) and Cu (10.6 mg kg^{-1}). The concentrations of Pb and Zn increased almost two-fold with increasing pyrolysis temperature from 300°C to 600°C . All metals, except for the concentration of Zn in the bamboo biochar pyrolyzed at 600°C , were less than the ambient background concentration as defined by the International Organization for Standardization, ISO (ISO, 2005).

Organic contaminants can also be generated during pyrolysis. The benzo(a)pyrene group and other PAHs are persistent; they form as a result of incomplete combustion. Two fundamental mechanisms lead to their formation during slow pyrolysis: (i) condensation, carbonization, and aromatization of solid materials at temperatures $<600^\circ\text{C}$, with a peak at 500°C , and (ii) pyrosynthesis, during which gaseous hydrocarbon radicals generated at temperatures $>500^\circ\text{C}$ react to form polyaromatic ring structures, with the dominance of PAHs in tar and gas over the solid phase. Low-molecular-weight PAHs (with two or three rings) are usually formed at temperatures $<500^\circ\text{C}$, whereas the high-molecular-weight PAHs (five and six rings) are produced at temperatures exceeding 500°C . Naphthalene and phenanthrene usually comprise the largest contributions to total PAHs in biochars.

Recorded concentrations of PAHs vary widely. Small concentrations ($\Sigma 16$ EPA: Environmental Protection Agency has identified the 16 most frequently occurring and/or dangerous PAHs as priority pollutants) of $0.07\text{--}3.27 \text{ mg kg}^{-1}$ in 50 biochars produced at temperatures between 250°C and 900°C from manure, paper-mill waste, pine wood, and maize straw, and $<0.5 \text{ mg kg}^{-1}$ in 11 biochars from five different feedstocks. In contrast, large concentrations have been reported: $1.2\text{--}19 \text{ mg kg}^{-1}$ in 11 biochars produced from sawdust, maize stover, and wood waste at temperatures ranging from 350°C to 850°C , and 64.7 mg kg^{-1} in rice-husk biochar and 145 mg kg^{-1} in a pinewood charcoal.

Wood gasification gives rise to the largest concentrations of PAHs because the compounds undergo condensation in solid residues at the high temperatures prevailing. The amounts of PAHs in biochar can be minimized during production by separation of the gases, and the process can be controlled at high temperatures to produce biochars with small concentrations of PAHs. A wide range of waste feedstocks can be pyrolyzed at temperatures $>500^\circ\text{C}$ to produce biochars that (i) have concentrations of PAHs less than soil background concentrations, and (ii) have low bioavailability of PAHs. Furthermore, although some biochars can have large concentrations of PAHs that exceed established limits in the standards, the PAHs are largely unavailable to biological organisms because they are strongly adsorbed on biochar surfaces. The biochars act more as a sink than as a source of PAHs, and hence they can be used to sequester PAHs that happen to be in the soil.

Polychlorinated dibenzo-p-dioxins and -furans (PCDD and Fs) can form when a biomass containing large concentrations of chlorine is pyrolyzed. For example, pyrolysis of food wastes containing salt (2.9% Cl) were found to produce a toxic dioxin concentration of 1.2 pg g^{-1} TEQ (toxic equivalency). Plants growing in salty soil or irrigated with saline 'gray' water with large concentrations of chlorine ($>1\%$ Cl) can produce biochar with large concentrations of PCDD and Fs. If feedstocks with only small concentrations of Cl are selected, then the biochar itself produced should contain small PCDD and F concentrations and comply with the standards for organic contaminants.

Remediation of contaminated soil

Biochars can sorb many contaminants, both inorganic such as heavy metals, ammonium, nitrate, phosphate, and organic including agricultural chemicals, antibiotics, PAHs, polychlorinated biphenyls (PCBs), volatile organic compounds (VOCs) and aromatic dyes. They immobilize cationic trace metals, primarily by adsorption and precipitation. At soil pH more acid than their points of zero charge, biochars are expected to be positively charged and to adsorb anionic pollutants, such as nitrate (NO_3^-), phosphate (PO_4^{3-}), arsenate (AsO_3^-) and chromate (CrO_4^{2-}). Organic contaminants are retained by biochars with chemical interactions on surfaces and in pores, and highly porous biochars with abundant aromatic structures and functional groups adsorb organic compounds in various ways. The interactions of organic contaminants with biochar can involve inner- or outer-sphere complexation and other processes such as pore diffusion, van der Waals forces, H-bonding, π - π electron donor-acceptance, universal electrostatic attraction between non-polar molecules (London dispersion forces) and attraction between polar molecules (dipole-dipole forces) involving COOH and OH functional groups. Organic contaminants sorbed on biochars are eventually degraded by microorganisms.

The capacity of biochars to sorb and immobilize contaminants in soil and water depends on their characteristics, which, as above governed by pyrolysis temperature, feedstock and other treatments. In general, biochars pyrolyzed at high temperatures ($>500^\circ\text{C}$) have larger specific surface areas, microporosity, condensed aromaticity and hydrophobicity, and therefore a greater affinity for organic contaminants. Specific surface areas of biochars made from rice straw are reported as $19.7 \text{ m}^2 \text{ g}^{-1}$ pyrolyzed at 400°C , $44.0 \text{ m}^2 \text{ g}^{-1}$ at 500°C and $193.2 \text{ m}^2 \text{ g}^{-1}$ at 600°C . The adsorption of the insecticide cyromazine (N-cyclopropyl-1,3,5-triazine-2,4,6-tri-amine) on biochars also increased with increasing temperature; it was greatest for the biochar produced at 600°C .

Fig. 9 Sorption of As, Cd, Cu, Pb and Zn on a wood biochar (*Eucalyptus saligna* Sm.) pyrolyzed at 550 °C from initial loadings of the trace elements between 2 and 800 mmol at an initial solution pH = 7 and in the presence of 0.01 m Ca(NO₃)₂ as a background electrolyte. From Namgay T, Singh, B and Singh BP (2010) Influence of biochar application to soil on the availability of As, Cd, Cu, Pb, and Zn to maize (*Zea mays* L.). Australian Journal of Soil Research 48: 638–647.

Not all consequences of the addition of biochar to soil are desirable. Fresh biochars, due to their hydrophobic surfaces and large internal surface area, have a strong affinity for organic herbicides and pesticides. These agrochemicals can be less effective than intended where biochar has been applied at large rates (>20 t ha⁻¹), the amounts of the chemicals need to be adjusted accordingly in soil amended with biochar. In time the surfaces of the biochar become oxidized and hydrophilic, and its effect attenuates or even reverses.

Biochars produced at low pyrolysis temperatures (<500 °C) are generally preferred for the adsorption of inorganic contaminants because they have functional groups with which to react. A biochar produced at 350 °C was found to be more effective than a high temperature biochar in retaining trace metals, Pb²⁺ and Cu²⁺, in an acid soil. It seems that functional groups on the surfaces of the biochars retain cationic trace metals in the soil. The following sequence of sorption of trace elements on biochar made from eucalyptus (*Eucalyptus saligna* Sm.) wood at 550 °C has been reported as Pb > Cu > Cd > Zn > As (Fig. 9; Namgay et al., 2010). The pH of the equilibrium solution increased with increasing sorption of the cations which suggested a cation exchange reaction involving metallic cations and H⁺ ions. There was an increase in the solution's pH in the presence of As, possibly because of exchange between arsenate (AsO₄⁻) and hydroxyl (OH⁻) ions on biochar surfaces.

Producers can now customize biochars for specific applications. They can make biochars from high-quality woody feedstocks and activate the surfaces after pyrolysis so that the product will remove both cationic and anionic contaminants from water and contaminated soil at a moderate cost. In one case, biochar made from willow feedstock sequestered organochlorine pesticides at old sheep dip sites that were also contaminated with As.

Biochar in composting of biological wastes

Producing biochar from waste, instead of composting it, can significantly reduce emissions of greenhouse gases. Composting produces CH₄ and N₂O. The IPCC (2006) has set default emissions for the composting of biological wastes; they are 10 g CH₄ and 0.6 g N₂O per kg dry waste. The wetness of many of these wastes, such as municipal green waste, waste food, sewage sludge and animal manure, make them unsuitable for biochar production, however. Wastes suitable for biochar can be separated from those better suited for composting. The biochar can then be used as a bulking agent during composting, and the combination produces less greenhouse gas and recycles nutrients for agricultural crops. Reduction in emissions of both CH₄ and N₂O during composting are estimated to be 80% under the most favorable conditions.

Porous and reactive surfaces of biochar provide an aerobic environment and improve the structure of the composting pile, and that change stimulates aerobic microorganisms (e.g., methanotrophs and nitrifiers), increases the oxidation of C to CO₂ and N to NO₃⁻, favors the retention of nitrogenated molecules on biochar surfaces, and decreases emissions of CH₄ and N₂O. It has also been found that addition of biochar to composting substrate reduced losses of total N by 30.2%, NH₃ by 52.6% and N₂ by 66.2%.

The amount of CH₄ produced depends strongly on the proportion of biochar in the compost and characteristics of the organic residue in the composting process. Reported examples include a 55% reduction in CH₄ emission when chicken manure was composted with 20% biochar, and reductions of >70% and >80% were reported for cow manure and municipal solids, respectively, when composted with 10% biochar. Small (3%) proportions of biochar in the mixture of poultry manure (78%) and barley straw (22%) had no significant effect on the emission of CH₄. Evidently, some larger proportion is needed to have a significant effect.

Conclusions and the future

Biochar is rich in carbon (C) and long-lasting in soil. When produced from organic wastes or other feedstock and added to soil, it represents a site of sequestered C. To have a net benefit requires that production of CO₂ is minimized, it must be produced from renewable feedstock grown purposefully for it or from waste materials close to the place where it is made and used. The benefit can be quantified by a Life Cycle Assessment.

The chemical composition, pH, liming potential, pore volume, bulk density and specific surface area, which determine the main characteristics of biochars, are highly variable. They depend on the feedstock, the conditions of pyrolysis, in particular the temperature during which it is made, and treatment thereafter. These should be standardized, and production planned to achieve the desired qualities for particular applications. Addition of biochar to soil increases the soil's porosity (and decreases its bulk density) and hydraulic conductivity.

Biochar contains plant nutrients and carbonates in its ash. It is therefore valuable as a fertilizer and a liming agent, especially in light textured, acid soil poor in organic matter. Long-term field studies are still needed to evaluate the durability of these effects and resolve conflicting evidence from existing trials.

Most field experiments on biochar have shown that its addition to soil has resulted in increased crop yields, especially when applied with mineral fertilizers (compared with fertilizer only application). The increases depend on the properties of both the soil and the biochar and its rate of application, and weather.

Some biochars contain large concentrations of toxic elements and organic compounds, which might enter the food chain and could affect soil biota. Both the feedstock and the pyrolysis process must be properly controlled so that concentrations of toxic elements, in particular heavy metals, and organic toxins are kept within specified bounds for intended applications of the biochar.

Biochar can bind contaminants, particularly toxic organic contaminants from industrial and waste water. This makes them valuable for restoring polluted lands. Trials at the field scale are still needed to confirm the results of many laboratory and glasshouse studies.

As biochar-based fertilizers are being introduced in some countries, such guidelines need to be developed to ensure that the fertilizers are as effective as claimed for increasing crop yields and cutting emissions of greenhouse gases.

Abstract

Soil dissolved organic carbon (DOC) is a small but important fraction of total soil carbon that is involved in an enormous variety of important interactions with plants, microbes, and minerals. DOC is composed of thousands of individual compounds with differing sizes, reactivities, and functions, and is fundamental to soil forming processes. The reactivity of DOC with mineral surfaces changes depending on each molecule's functional groups, shape, and the composition of the soil solution. Adsorption is a dominant fate of DOC, but adsorption reactions are reversible and aged DOC may be released and exported from soils to groundwater and fluvial networks.

Introduction

Soil dissolved organic carbon (DOC) is generally a small fraction of the total soil C pool at any given time but is of considerable relative importance in shaping soil ecosystem function and properties. The impact of DOC lies not in its total amount, but that it is reactive, dynamic and mobile, and over time helps shape the distribution and nature of total soil C. Most current global studies of C focus on atmospheric and plant C pools and dynamics. However, total soil C (to 1 m depth) exceeds the total amount of C in plants and the atmosphere globally. When soil depth is extended further, the amount of soil C generally increases, forming a huge global C pool little studied, or even quantified, and much less well understood, especially in terms of its properties and dynamics.

Soil DOC has high mobility and reactivity and can act as a carbon and energy source for soil heterotrophic organisms deeper in the soil profile. Though soil water, and thus DOC, can and does move in all directions in soil, movement downward into the soil profile is the prevalent DOC transportation mechanism in humid regions, and one of the primary mechanisms resulting in the formation of unique soil profiles. Soil DOC both affects and is affected by the soil solid phase as it moves through it, adding to chemical and biological weathering of soil parent materials, acting as a carbon and energy source for soil microorganisms, and stripping or depositing byproducts of soil weathering as it moves through a soil profile. Soil leaching can further move C and soluble products of soil weathering completely out of the soil profile, potentially to groundwater, or into aquatic ecosystems such as streams and lakes.

DOC is the most dynamic and mobile pool of total soil C. Much of soil C has formed and accumulated over relatively long periods of time. Under conditions of climate change, expected impacts include shifting human, plant and animal populations and associated land-use changes, invasive species spread, extinctions, and altered temperature and precipitation. Consequently, assuming soil C and especially soil DOC will remain constant in the future is risky, particularly in assessing feedbacks between soil C and the global climate. Changes in the rates of formation of DOC in soil and its movement into the soil profile could greatly impact total ecosystem C and global soil C.

Definition

Soil DOC is typically defined empirically, with the specific definition in each instance depending on methods of collection and determination. Soil DOC is by nature highly variable chemically, biologically, and physically, which can result in some ambiguity in definition. For example, to collect soil DOC, a sample of soil solution is taken, either by extraction or centrifuging, and soil solution C which will pass through a filter with a pore size typically 0.2–0.7 μm is then defined as “soil DOC”. As such, soil properties can significantly affect what will remain in solution. The most important soil properties determining soil DOC — usually soil surface charges (cation exchange capacity, CEC, and anion exchange capacity, AEC), pore size, soil solution composition, and other properties, particularly those that enhance hydrophobic adsorption (Jardine et al., 1989; Kothawala et al., 2008) — bind C molecules to soil surfaces that might otherwise remain in solution. Aging of soil extracts can also affect operational soil DOC, since C molecules are typically chemically active, and can undergo precipitation or fractionation that can change a molecule’s ability to pass through a filter.

The method of DOC collection in the field or extraction in the laboratory can substantially affect the quality and quantity of measured values, and consequently care is necessary in interpreting the literature. For example, DOC measured from soil lysimeters in the field is typically less concentrated than DOC extracted by centrifuging soils in the laboratory, which in turn are less concentrated than soil extracted with mild salt solutions or hot water under vacuum. Due to these differences, laboratory extracted DOC is frequently identified as water extracted organic carbon (WEOC) to avoid confusion with field-collected DOC. When soil solution is collected by extraction, usually with tension soil lysimeters, it will already be filtered depending on lysimeter pore size, and any carbon in the solution may be defined as dissolved. In common use, the terms soil DOC and soil dissolved organic matter (DOM) are sometimes used interchangeably, with soil DOC typically reported as the mass of C only and DOM as the total mass of dissolved material. The fate and reactivity of DOC depends not just on the structure and type of carbon-to-carbon bonds, but on the kind, quantity, and bonding orientation of other elements within the molecular structure, particularly hydrogen, oxygen, phosphorous, and nitrogen. Thus, discussions in this chapter about mineral-organic interactions, as well as fate and transport will focus on soil DOM rather than just DOC.

Origins of DOC

Dissolved organic carbon enters soil systems through rainfall, plant residues, root exudates, desorption or degradation of soil organic matter (SOM), and microbial biomass (Gmach et al., 2020). Plants contribute to soil DOC through the breakdown of plant debris by soil organisms both large and small as well as deliberate release of soluble organic molecules by plant roots, including facilitation of mutualistic relationships with microbes. Once this plant derived material enters solution, it becomes food for a complex ecosystem of fungi, bacteria, and archaea (Sylvia et al., 2005). These microbes consume and transform plant-derived DOC and release a variety of organic substances including communication molecules and extracellular enzymes (while alive) and a host of compounds after cell death and breakdown of cellular structures. In mineral soils, where plant residues mostly accumulate at the surface, DOC most closely resembles plant-derived molecules near the surface and gradually transforms with depth to resemble microbially-derived DOC (Kaiser and Kalbitz, 2012). A portion of DOC observed in soil solution is derived from old, solid-phase SOM which is released through desorption or partial microbial degradation of surface-bound SOM (Leinemann et al., 2018).

The relative importance of each input of DOC varies between soils and ecosystems, as well as the depth within the soil profile. For example, surface litterfall in a coniferous forest resulted in considerable DOC movement from surface litter into mineral soil, accounting for 22% of annual carbon inputs below 40 cm (Sanderman et al., 2008). In a contrasting grassland, surface litter accounted for only 2% of carbon inputs below 20 cm, which instead was dominated by inputs from root exudates and turnover. In both soils, field collected DOC was significantly aged (based on radiocarbon dating), indicating that DOC in solution was not simply the fraction of surface-derived DOC remaining in solution but that there must be exchange with older SOM with residence times of decades to centuries (Sanderman et al., 2008). Adsorption was the dominant fate of DOC once it entered the soil, with mean residence times of 90–150 years.

Rainfall provides a small but important input of DOC to soils. Approximately 80% of carbon in rainfall is organic, and rainfall deposits approximately 0.5 Pg C y^{-1} , of which 70% is over land (Willey et al., 2000). Beyond carbon input, the duration, quantity, and intensity of rainfall affects DOC movement and flux in soil by affecting the hydrologic dynamics of soil solution.

Factors associated with DOC inputs and production

Climate

A compilation of DOC from 365 soils in different ecosystems around the globe found that temperate climates — generally found between 35 and 60°N latitude — had, on average, the largest DOC concentrations (Fig. 1; Camino-Serrano et al., 2014). Despite the enormous productivity of tropical ecosystems, tropical soils (<35°N latitude) had the smallest average DOC concentration. Boreal soils had similar DOC concentrations in surface soil compared with temperate soils, but smaller subsurface concentrations (Camino-Serrano et al., 2014). The differences between these broad climate classes reflect offsetting, climate-dependent processes: DOC production and DOC decomposition (Kalbitz et al., 2000). The rate of DOC production is weakly related to temperature, but

Fig. 1 Distribution of DOC in mineral soils by latitude and climate classification. Whole soil average with 95% confidence intervals are shown at the top for each group. Redrawn with data from Camino-Serrano et al. (2014).

also depends upon the nutrition available to soil microbes as well as the composition of decomposing plant matter, such as lignin content (Moore et al., 2008). In contrast, the ratio of CO_2 :DOC production increases steeply with temperature (Moore et al., 2008), which suggests that high DOC production in the tropics is offset by high decomposition rates. In boreal soils, low temperatures reduce both DOC production and decomposition. Temperate soils thus maintain larger DOC concentrations due to the balance of greater rates of DOC production than boreal and arctic soils but smaller rates of decomposition than tropical soils (Camino-Serrano et al., 2014).

DOC concentrations exhibit seasonal fluctuations. This effect is more pronounced in surface soil and muted in the subsurface (B and C horizons) due to greater microbial activity in surface soil, which is partly controlled by temperature (Kalbitz et al., 2000). Due to elevated microbial activity in the growing season, larger concentrations of hydrophilic compounds derived from microbes and carbohydrates are released into soil solution (Guggenberger and Zech, 1994). Soil moisture is also a significant factor in seasonal fluctuations in soil DOC. After dry periods, studies have consistently identified a flush of DOC upon rewetting, likely from mobilization of microbial products that accumulated on soil surfaces or in mineral-associated pore water (Kalbitz et al., 2000).

Soil type

Organic peatland soils typically have the greatest concentrations of DOC because they are composed of a large reservoir of incompletely decomposed plant material (Fig. 2, Camino-Serrano et al., 2014). Unlike mineral soils, DOC concentrations increased with depth in non-forest organic soils. Despite the great quantity of plant material and DOC available for decomposition in organic soils, complete water saturation and low rates of oxygen recharge greatly slow microbial activity. Decomposition is an oxidation-reduction (redox) process where organic matter is oxidized (loses electrons) and oxygen atoms are reduced (accept electrons). As redox conditions decline with depth in organic soils, alternative electron acceptors are used by different varieties of microbes. Nitrate, manganese oxide, iron, sulfate, and carbon dioxide are used as alternative electron acceptors in decreasing order of energetic yield and rates of decomposition (Sylvia et al., 2005). The residence time of water also increases with depth in organic soils, which allows DOC to build up even though DOC production rates are slow due to highly reducing and anaerobic conditions (Camino-Serrano et al., 2014).

The effect on DOC concentrations of different mineral soil types depends on their texture and mineralogy, particularly the capacity to adsorb DOC on mineral surfaces. Camino-Serrano et al. (2014) observed that volcanic soils had the smallest DOC concentrations, on average, and attributed the difference to widespread sorption of DOC to minerals (iron and aluminum oxides) derived from volcanic ash. In comparison, weakly developed soils with coarse or sandy textures such as Podzols, Arenosols, and Regosols (FAO soil taxonomy) (Spodosols and Entisols in USDA taxonomy) had the greatest concentrations of DOC among mineral soils (Camino-Serrano et al., 2014). Sand particles have small surface area relative to their volume and little capacity to adsorb organic molecules. The effects of differing mineralogy on DOC dynamics will be detailed below in the discussion of adsorption.

Fig. 2 Distribution of DOC by organic or mineral soil type. Whole soil average with 95% confidence intervals are shown at the top for each group. Redrawn with data from Camino-Serrano et al. (2014).

pH

pH is a dominant control over the electrical charge on both organic molecules and soil minerals, including clays and iron and aluminum (hydr)oxides. DOC release from organic soils is positively correlated with pH, likely due to protonation of organic functional groups at low pH which reduces solubility (Tipping and Woof, 1991). In mineral soils, by contrast, soil solution DOC is enhanced in more acidic soils, especially in subsurface layers below 10 cm (Fig. 3; Camino-Serrano et al., 2014). Low pH in mineral soils encourages saturation of exchange sites (e.g. with protons and exchangeable aluminum) and dissolution of organic complexes containing polyvalent cations (Kalbitz et al., 2000), both of which reduce adsorption.

Quantity and quality of organic material

The quantity and quality DOC differs between coniferous and broadleaf forests (Fig. 4), although the reasons may not be directly due to the forest type. Broadleaved trees tend to produce less acidic litter, and changes in soil acidity have a profound effect on the composition and activity of soil microbes. Consequently, conifer forests may have slightly greater soil DOC because of altered soil metabolism. However, forest composition is not independent of the soil and climate conditions in which the forest grows. Conifers, especially pines, are more frequently located on sandy soils and in cold climates. In sandy soils, the flow regime and fast transport through macropores dominates DOC dynamics, possibly reducing adsorption and microbial processing (Kalbitz et al., 2000). Cold temperatures likewise inhibit microbial activity, resulting in greater concentrations of DOC remaining in solution. All three mechanisms – inherent differences in microbial processing of litter from different trees, hydrological controls on DOC transport, and temperature dependence of both microbial processes and tree species growth ranges – co-occur and are difficult to disentangle (Camino-Serrano et al., 2014).

Soil use and management

The enormous extent and intensity of human use of land and soil is readily visible on any airline flight or through satellite imagery. The UN FAO estimates that currently 38% of global land area is used for agriculture, about a third of which is cropland and two thirds of which is permanent meadow and pasture (UN FAO, 2021). In many parts of the world, forestland is also increasingly utilized. Much of the rest is either urban or not considered arable. As world population has increased since 1960, land use for agriculture has not increased greatly in actual area, but intensity (humans fed per hectare) has nearly doubled since 1960, primarily through genetic improvement of plants, but also increased use of fertilizers and pesticides (UN FAO, 2021). This increased agricultural intensity strongly affects the amount and molecular composition of DOM, which constitutes the main vector of carbon

Fig. 3 Distribution of soil DOC by pH classification, excluding Histosols (organic soils). Whole soil average with 95% confidence intervals are shown at the top for each group. Redrawn with data from Camino-Serrano et al. (2014).

transport from soils to freshwater systems and to the ocean and is involved in a large variety of biogeochemical processes. For example, Graeber et al. (2015) found that DOM exported from agricultural catchments had a more microbial and less plant-derived composition, and was accompanied by greater dissolved organic nitrogen (DON), which together could drive greater CO₂ outgassing in freshwater systems.

There is some additional arable land available, but the trend of increased production per hectare needs to continue so that much of that area can be preserved, and hopefully also to allow some land currently being utilized to be allocated for conservation and preservation. Understanding the implications for soil C in land areas under more intensive agriculture is essential to any future management. If greater intensity of management causes shifts from solid-phase to soluble soil C, the implications could be enormous both for future productivity and global C (Paustian et al., 2016).

Composition and transport of dissolved organic matter

Composition

DOM consists of hundreds to many thousands of individual compounds, each of which have different sizes, reactivities, functional configurations, and solubilities. Due to the complexity of the mixture in solution, a wide variety of methods have been developed to probe DOM composition. For example, fluorescence spectroscopy generates a signature of the subset of organic compounds that can absorb a photon of light and re-emit a photon at a different wavelength. Other techniques, such as mass spectrometry, differentiate distinct compounds by weight, with some advanced methods that can tentatively identify each of thousands of molecular formulas contained within a DOM mixture (for example, Fourier-transform ion cyclotron resonance mass spectrometry, or FTICR-MS). Yet, knowing many of the molecular formulas for compounds does not reveal critical features of molecules that would be necessary to completely understand their reactivity, such as the structure and conformation of the molecule. Due to the diversity of methods old and new, there are many classification schemes for DOM compounds based on perceived, inferred, or measured properties, including recalcitrance and lability (how quickly each compound will biodegrade), bioavailability, aromaticity, size, and even inferred origin (Xenopoulos et al., 2021).

Many organic molecules have been extensively studied, particularly toxic and potentially hazardous chemicals such as benzene, naphthalene, polycyclic aromatic hydrocarbons (PAHs), or other organic pollutants monitored by the U.S. EPA, European Chemicals Agency (ECHA) and other regulatory agencies. Understanding the chemistry of these molecules is critical for designing engineering systems and remediation plans to safeguard the public following historical or contemporary industrial releases. In contrast, much less is known about the many thousands of natural organic compounds found in soil DOM, including the biodegradation products of hydrocarbons and other contaminants.

However, there are unifying features of many organic molecules in solution that permit a general understanding of the controls and interactions that DOM undergoes with soil minerals. For example, natural oils and waxes contain long, linear or branching chains of carbon atoms that do not have an electrical charge (called aliphatic). Regardless of the length of the chain or what other organic structure is attached, that portion of the organic molecule is not attracted to polar water molecules and will preferentially separate itself from solution. Other organic molecules, such as those containing specific functional groups like carboxylic acids, aldehydes, or alcohols, can have negative charges depending upon soil solution pH, which will cause them to interact with ions in solution and charged mineral surfaces. Likewise, dissolved organic molecules containing amine groups (e.g., amino acids) can maintain positive charges.

Transport

The movement of DOM depends upon both the soil type and mineralogy within the soil profile, as well as the hydrologic connections, location, slope, and aspect of soils in the landscape. In most soils, rainwater percolates through the surface and is transported downward by gravity until reaching the water table. In some soils (both mineral and organic) the topography is flat and water table is near or at the soil surface, in which case the rate of movement of water within the profile can be slow. The transport of DOM in soil water is also affected by capillary forces (the attraction of water molecules to soil surfaces), which can keep small pockets of water (and DOM) in place under draining conditions. Above a water table, capillary action in soil draws water upwards, together with the DOM and dissolved inorganic carbon (DIC, such as carbonic acid and bicarbonate) contained in it. In areas where evapotranspiration exceeds precipitation and the pH is alkaline, inorganic carbon rather than DOC may be the dominant form of carbon in solution, which allows carbonate minerals to precipitate and accumulate in the soil profile.

The movement of DOM within the soil profile does not simply follow the flow of water. DOM released from plant materials or roots at or near the surface interact with minerals and microbes, resulting in slowed movement, partial decomposition, and transformation (Fig. 5). Near the soil surface, particularly the organic rich O and A horizons, DOM has modern or near-modern radiocarbon signatures, and thus is likely the product of recent photosynthetic products (Sanderman and Amundson, 2008; Froberg et al., 2009). In contrast, studies around the globe across diverse ecosystems have observed that subsoil DOM is depleted in radiocarbon. Thus, subsoil DOM is composed of older compounds or compounds containing pieces of aged carbon, and little DOC derived from the surface reaches mineral subsoil (Froberg et al., 2009; Hagedorn et al., 2015). In fact, labeled DOC leached through

Fig. 5 Cycling of dissolved organic matter in soils through a cascade of interactions. The processes depicted take place in a continuum throughout the soil profile. Photosynthetic carbon comprises organic products of plant photosynthesis released to the soil through plant litter or roots. Polymeric non-soluble organic matter is composed of larger particles or molecules of organic matter that are not in soil solution. Under most circumstances, CO_2 is the primary respiration product of microbial consumption and oxidation of organic matter; CH_4 may be created and emitted only under highly water-logged and reducing conditions. CH_4 generated in soil may not be released into the atmosphere as microbes that produce and consume CH_4 frequently co-occur (Kaiser and Kalbitz, 2012).

soil columns revealed that almost all was retained in soil due to mineral interactions, with the label concentrated along preferential flow paths in deeper soil (Hagedorn et al., 2015). DOM moving through the soil profile is subject to a stepwise cascade of reactions and interactions, including adsorption to minerals, microbial transformation and degradation, and re-release of DOM into soil solution during transport down the soil profile (Kaiser and Kalbitz, 2012; Leinemann et al., 2018).

Interactions with minerals and microbes

Effect of DOM composition on organo-mineral interactions

Advances in analytical techniques over the last two decades have allowed identification, within individual DOM samples, of tens of thousands of different organic compounds with widely varying molecular structures, sizes, and functional groups. The differences in the structure, size, and functionality of different molecules within DOM result in diverse modes of interaction with mineral surfaces in soil (von Luetzow et al., 2006). Aliphatic organic molecules, which are chains of single or double-bonded C atoms without other functional groups, such as hexane (C_6H_{14}), as well as aromatic molecules, which contain one or more 6 carbon rings, such as benzene (C_6H_6) and naphthalene (C_{10}H_8) can bind to mineral surfaces through hydrophobic exclusion: non-polar molecules will associate with one another away from water, which is inherently polar. This interaction is pH independent, whereas most other modes of organic attachment to minerals are pH dependent (Jardine et al., 1989; Kleber et al., 2007). Some aliphatic and aromatic molecules contain minor functional groups, such as hexanol ($\text{C}_6\text{H}_{13}\text{OH}$), which adds an alcohol (OH) group to hexane, and benzoic acid ($\text{C}_6\text{H}_5\text{OOH}$), which adds a carboxyl group to benzene. In addition to hydrophobic interactions, the polar ends of these molecules can attach to minerals through hydrogen bonding. If these molecules lose a hydrogen atom, they become negatively charged and will seek to satisfy this charge with positive charges on mineral surfaces or metal cations. Some organic molecules such as glucose ($\text{C}_6\text{H}_{12}\text{O}_6$) are inherently polar with no aliphatic or aromatic structures and will primarily interact with minerals through hydrogen bonding (Kleber et al., 2021). However, the additional functionalization of these kinds of molecules, as in glucosamine ($\text{C}_6\text{H}_{13}\text{NO}_5$) or gluconic acid ($\text{C}_6\text{H}_{12}\text{O}_7$), will allow the molecule to become negatively charged (for gluconic acid) or positively charged (for glucosamine) and thereby interact with minerals through electrical forces of attraction. Positive charges in DOM mostly

occur with N-containing groups due to the ability for -NH_2 groups to attract an additional proton to become -NH_3^+ . Finally, some DOM molecules, such as the amino acid phenylalanine ($\text{C}_9\text{H}_{11}\text{NO}_2$) as well as many proteins and polypeptides, contain all major functionalities and may interact with minerals in numerous ways depending upon the pH of the soil solution (Kleber et al., 2021).

The quantity and composition of soil DOM also effects the mobility and bioavailability of metals in soil. DOM molecules containing multiple negative charges can completely satisfy the positive charges of multivalent cations (e.g., Al^{3+} , Cd^{2+} , Fe^{2+} , Ni^{2+} , Zn^{2+}) through a process called chelation. Chelated metals are subsequently transported with the soluble organic molecule until such time as the molecule is degraded by microbes, immobilized by organo-mineral adsorption, or environmental conditions change, such as increasing solution pH. Organic interactions with and translocation of Fe and Al are essential reactions during pedogenesis. For example, the soil forming process called podzolization, which results in some of the most visibly striking and photogenic soils across the globe, is a direct result of metal chelation, transport, and deposition through DOM interactions (Lundström et al., 2000). During podzolization, dissolved organic acids from low-pH plant litter at the soil surface gradually strip away Fe and Al from the surface mineral soil, forming a gray, eluviated (E) horizon. As the organic acids leach downward, buffering of soil solution gradually raises the pH, which reduces the quantity of pH-dependent negative charges present on DOM. Subsequently, chelated iron is released and precipitates as ferrihydrite or goethite minerals, and chelated aluminum is released to form allophane or imogolite minerals through interactions with silicon (Ugolini and Sletten, 1991). The quantity and identity of metals mobilized by DOM in any specific soil or watershed depends upon the full suite of soil forming factors (climate, parent material, topography, organisms, and time) and the composition of DOM in solution.

Adsorption

Adsorption encapsulates a series of kinetic and electrochemical processes, namely diffusion, competition, and exchange of organic molecules at mineral surfaces. Adsorption processes are dynamic rather than static or irreversible (Kleber et al., 2021). The interface between DOM and minerals continuously evolves, based on changes in the composition of DOM in soil solution and the chemical composition of soil solution over seasons and years, as well as being mediated by biota, including both plant roots and microbes.

DOM adsorption processes are inherently diverse due to convolution in the spatial arrangement of the reactants and complexity in the composition of DOM and clay minerals (Fig. 6). At the large scale, soil minerals compartmentalize and structure the physical environment where organo-mineral interactions take place. Mineral soils contain a continuum of pore spaces with different sizes, morphology and connectivity depending on soil texture and the degree of soil development (e.g., age) (Six and Paustian, 2014). Larger particles, such as sand, provide fewer reactive surfaces than clays, but can provide macropores where water, DOM, and microbes can move relatively unhindered. On the other hand, the smallest micropores may restrict microbial access to DOM that would otherwise be consumable. Although gravity is the primary force driving water migration in macropores, water (and DOM contained in that water) near charged mineral surfaces will be increasingly bound and kept from transmission through the soil. Together these effects constrain the kinetics of mineral-DOM interactions by preventing or limiting spatial orientations that would be required for reactions to proceed unhindered and by limiting diffusion of organic molecules (Kleber et al., 2021).

Many interactions are possible between DOM and charged surfaces in soil. The observed diversity in adsorption processes is driven by the inherent variability of both the organic and inorganic reactants (Kleber et al., 2021). The strongest interactions involve ligand exchange, in which an organic adsorbate shares an oxygen with the crystal lattice of a clay molecule, most frequently an Fe- or Al-oxide. Negatively charged organic molecules in solution can interact with negatively charged clays by a cation 'bridge', wherein a cation with multiple positive charges (e.g., Ca^{+2} , Mg^{+2} , Al^{+3}) is attracted to both the clay and organic molecule (Fig. 6). Long-chain organic molecules without electrical charge may interact with charged surfaces by cation bridging as well, except involving monovalent cations (e.g., K^+) which have their positive charges mostly satisfied by the clay. Van der Waals forces attract uncharged, long-chain molecules to uncharged clay or other mineral surfaces. Hydrogen bonding, in which a polar bond between hydrogen and an electronegative atom (frequently oxygen) causes electrostatic attraction, can form bonds between an organic molecule and a clay surface or another organic molecule. Hydrogen bonding is typically stronger than van der Waals forces but weaker than cation bridging or ligand exchange reactions. Finally, long-chain, uncharged (aliphatic) molecules are frequently hydrophobic and will resist attraction to polar water molecules, which can cause them to form hydrophobic zones where these molecules partition together away from polar water or charged organic or inorganic structures.

DOM can partition out of solution to form multilayer assemblages with complex, layered structures at varying distances from a mineral surface (Kleber et al., 2007). The precise structure, distribution, and persistence of multilayer or zonal structures remains an area of inquiry. DOM molecules compete among each other and with inorganic ions for sorption sites. Even once a molecule has formed an adsorptive bond, they may desorb, although often with conformational changes to the structure of the organic molecule. Changes in soil pH, electron availability, or modifications to sorbent surfaces can induce desorption (Thompson et al., 2006). Plant roots can also exude organic molecules specifically to release bound organic matter as a means of making organic-bound nutrients more available (Keiluweit et al., 2015). Consequently, although adsorption to mineral surfaces is an important fate for DOM as it moves through soil, this fate is not irreversible (Leinemann et al., 2018).

Microbial processing, degradation, and communication

Microbial processes are critical to the release, processing, and composition of DOM. Microbes are present on and in plant litter when it drops to the soil surface, as well as intimately associated with plant roots. As soil macrofauna (such as millipedes, worms, etc.)

Fig. 6 Interactions between dissolved organic matter, minerals, and microbes. At large scales, the mineral matrix compartmentalizes the spaces where physiochemical processes can take place. Compartmentalization creates static and dynamic constraints on smaller-scale processes such as sorption and preferential pathways and transport pathways for DOM and microbes. Physical structures in soil (aggregates) can isolate adsorbed or polymeric organic matter from microbes, thus preventing decomposition. Less competitive microbial taxa may also be preserved in compartmentalized spaces. Mineral interfaces primarily interact with a diverse array of low-molecular-weight organic ligands that are produced through oxidative depolymerization of larger biomolecules (often plant derived). Near mineral surfaces, organic molecules can bind through one or multiple complexation mechanisms depending on the surface charge distribution, structure of the molecule, and competition with inorganic ions (such as PO_4^{2-}). Desorption of organic molecules from mineral surfaces is common, although with conformational changes to the structure of the molecule or mineral. There remain many unknowns with these processes, including the frequency and distribution of multilayer assemblages, the controls on susceptibility of adsorbed molecules to microbial degradation, and the selectivity and kinetics of desorption.

break down larger plant tissues and structures, microbial enzymes break down specific organic bonds to release smaller molecules that can be taken up by both microbes and plants. There is a complex interplay of both competitive and mutualistic relationships among microbes. In coarse sandy and gravelly soils, microbial species competing for the same compounds will lead to the dominance of the most successful species. However, in fine grained soils, species less well adapted to compete can survive in areas inaccessible to more competitive species, increasing overall soil microbial diversity (Kleber et al., 2021). Yet other microbes may be adapted to consume the degradation products of other microbes including the products of dead microbial cells. Typically, there is great functional diversity and redundancy in the soil microbial community, wherein enzymes from multiple microbes are needed to fully decompose organic matter, yet many different microbes use similar metabolic pathways and produce the same enzymes.

The ability of microbes to take up carbon from DOM or SOM and transform it into growth (rather than respiration) is called carbon use efficiency (CUE). Soils with high CUE have small respiratory losses and thus potentially can keep more C in the soil. Due to the importance of mineral-organic interactions in retaining DOM in soil, the microbial efficiency-matrix stabilization (MEMS) framework hypothesized that microbes filter DOM and particulate carbon inputs, delivering the organic products to the mineral matrix or respiring it to the atmosphere, thereby acting as the critical link between plant litter and stabilized SOM (Cotrufo et al., 2013). Because more recalcitrant plant litter is difficult to break down, it results in reduced microbial CUE, whereas litter that is prone to decomposition may enhance long-term SOM storage (Cotrufo et al., 2013).

In addition to breakdown of plant residues deposited at the soil surface, microbes associated with plant roots consume sugars and other molecules released from roots in exchange for nutrients. In forests, both arbuscular and ectomycorrhizal fungi are

intimately connected to plant roots. These symbionts fetch specific nutrients that would otherwise be unavailable to plants (e.g., in larger soil organic molecules or in minerals) in exchange for carbohydrates, amino acids, and other products of photosynthesis. The composition of microbial communities associated with roots, called the root microbiome, may be considered a secondary genome that provides host plants with microbe-derived compounds and traits. Plants can modify the rhizosphere bacterial community by modulating and adjusting the composition of root exudates, which in turn stimulate or inhibit different community members (Lareen et al., 2016).

The enriched soil around plant roots is a highly competitive environment for microbes. Consequently, microbes produce secondary metabolites (dissolved organic molecules of different types), including antibiotics that suppress pathogenic species (Lareen et al., 2016) and that can inhibit competitors occupying similar niches. There is also communication between fungal and bacterial cells and eukaryotic domains through the synthesis and diffusion of signal molecules that are subsequently perceived by other community members. Communication of this type is critical for both community coordination, such as forming biofilms, as well as regulating individual gene expression in response to changes in population density (Lareen et al., 2016). Thus, not only is soil DOM critical to soil C dynamics, but it is the primary medium of communication for the vast majority of living organisms on the planet.

Importance of DOC in the global carbon cycle

In addition to its role within soils, DOC is one of the primary conduits connecting terrestrial and aquatic ecosystems. The Intergovernmental Panel on Climate Change (IPCC) estimates that 2.5 Pg C y^{-1} is exported from the terrestrial biosphere to rivers (Canadell et al., 2021). While this estimate includes inorganic and particulate organics in addition to DOC, the total export is similar in magnitude to the present-day net uptake of atmospheric CO_2 by the oceans. Estimates of DOC export to oceans via freshwaters is approximately 0.20 to 0.8 Pg C y^{-1} and makes up 25–50% of C inputs to the oceans, depending on the river size and geographic region (Canadell et al., 2021; Williamson et al., 2021). An even greater quantity of DOC is processed within rivers without being delivered to oceans, either by burial in sediment or emitted as CO_2 to the atmosphere. The percentage of terrestrial gross primary production that is shunted to streams and rivers, where it is ultimately released as CO_2 to the atmosphere or buried in sediments, increases with river discharge, and emphasizes the importance of hydrology in the land-to-water transfer of carbon (Liu et al., 2022).

Organic peatland soils contain one third to one half of all SOC, despite occupying only about 3% of land surface area (Nichols and Peteet, 2019). They likewise contain the greatest concentrations of DOC (Fig. 2; Camino-Serrano et al., 2014) and yield the most DOC to rivers among soil types (Aitkenhead and McDowell, 2000). When wetlands or peatlands are artificially drained, the soil C and DOC, which were protected from degradation by the lack of oxygen, become much more susceptible to microbial breakdown and loss to the atmosphere. Consequently, the conservation, restoration, and protection of peatland and wetland soils is of special significance to the global carbon cycle.

Anthropogenic activities also impact mineral soils. While DOC and DIC are naturally exported from soils to some degree, human activities such as agriculture, urbanization, deforestation, and changes to drainage systems alter rates of organic matter oxidation and weathering, which can shift both the quantity and composition of riverine C exports (Butman et al., 2015; Xenopoulos et al., 2021). Anthropogenic activities have increased DOC and DIC export from soils to river by 0.2 to 1 Pg C y^{-1} , of which 80% is derived from soil (Regnier et al., 2013). The age of DOC in rivers has also been shown to increase with human population density and the proportion of human-dominated landscapes (e.g., agricultural, urban) within a watershed, with between 3% and 9% of DOC in rivers being aged carbon mobilized by anthropogenic activity (Butman et al., 2015).

Conclusion

Dissolved organic C (DOC or DOM) represents a relatively small but critically important pool of total soil C due to its highly reactive and mobile nature, relative to the bulk of soil C. Reactions of soil with DOC moving through the soil profile often defines the very nature of that soil profile, and is highly variable in location, climate, vegetation type, and season. Human use of soil, particularly for agriculture and urban development, is likely to change originally natural processes significantly, and in ways which we also do not currently well understand. Effects of human land use on DOC within soil profiles and exported from impacted catchments may serve as an early warning system of threats to total soil C, which is greater than all C in the atmosphere and all C in terrestrial plants, combined. Increasing study and understanding of DOC's importance as a dynamic determinant of total soil C (and thus global C) is critical to improving soil health and sequestering carbon from the atmosphere.

Abstract

Black carbon or pyrogenic carbon (PyC) represents a ubiquitous entity of soil organic matter (SOM). Presently, it is best described as a continuum of thermally altered biomolecules. The degree of their alteration depends on heat severity, heating conditions (oxic, pyrolysis), and the nature of the feedstock. Comparably, a paradigm shift occurred with respect to the biochemical recalcitrance of PyC taking into consideration that the latter depends not only on the degree of charring of the respective PyC but also relies on soil conditions. There is a clear effect on PyC properties (increasing pH, darkness, hydrophobicity, and plant nutrient contents), which can survive on a long-term scale. Thus, fire and biochar amendment may play an important role in pedogenetic processes.

Key points

- Definition and description of the nature of black carbon or pyrogenic carbon (PyC)
- Description of the processes involved in the formation of PyC
- Overview of the impact of PyC on soil properties and their distribution in soils
- Introducing a concept describing the interaction between soil conditions and the occurrence/survival of PyC in soils

Introduction

Black carbon or pyrogenic carbon (PyC) represents a ubiquitous entity of soil organic matter (SOM) and as such, it has a considerable effect on soil ecological functions but also on the role of soils within biogeochemical cycles. It has been calculated that it amounts to 54–109 Pg of PyC within the first meter of soil (Bird et al., 2015). For U.S. agricultural soils about 35% of the SOM (Skjemstad et al., 2002) and between 4% and 18% of organic carbon in soils under native grassland are reported to be PyC (Glaser and Amelung, 2003). An estimate of the global distribution of PyC in the soil, atmosphere, and marine sediments can be found in Santin et al. (2016). In soils close to highly industrialized or coal mining areas, contributions from residues of fossil fuels and soot cannot be excluded. A further important PyC fraction in soils derives from ancient charcoal inputs. The effect of ancient charcoal from human activity during Neolithic times has been evaluated by Eckmeier et al. (2007), but there is also increasing interest in the impact of PyC on soil properties around former charcoal kilns. Indeed, PyC has been considered a defining property of the Terra Preta de Índios soils in South America. Its positive effect on soil fertility and the high biochemical recalcitrance of PyC initiated the idea of amending artificial biochar produced from biowaste as a soil improver and tool for increasing the C sequestration potential of soils. Based on this trend, it has been estimated that biochar production may add an additional 110–220 Tg of C per year to the soil (Woolf et al., 2010).

The dynamics of PyC in soils are largely influenced by the physical and chemical structure of the charred material. It can change soil properties such as nutrient availability, pH and the quality and quantity of SOM. Today, post-harvest burning and application of biochars as soil conditioners take advantage of the beneficial effect of PyC on soil fertility. Current scientific interest in PyC produced during vegetation fires is directed more to its role within the global carbon cycle, whereas much of what we know about the chemical structure and physical properties of PyC derives from research on biochar production and its amendment to soils.

Definition of black carbon and the black carbon continuum

Chemically, black carbon is defined as a component of fine particulate matter ($PM \leq 2.5$ in aerodynamic diameter) and consists of almost pure carbon with some oxygen and hydrogen bound into layered, hexagonal structures. It is a soot-like by-product formed during incomplete thermal decomposition of fossil fuels, biofuel, and biomass or by recondensation of volatile compounds formed during this process. The thermal degradation can be done by combustion, which means in the presence of oxygen or by pyrolysis during which oxygen is absent or nearly absent.

In soil and environmental sciences, the term black carbon is not limited to describing soot and soot-like compounds, but is also a continuum of pyrogenic organic materials (PyOM) from slightly to heavily charred organic residues. Thus, this so-called black carbon continuum comprises a wide range of charred biomass formed during natural and man-made vegetation fires, and also charcoal produced primarily for soil amendments and carbon sequestration. The nature of this material depends on the feedstock, production temperature and conditions. Man-made black carbon is often known as biochar. The latter is commonly abbreviated to BC, therefore, the abbreviation PyC is used for the term black carbon throughout this chapter to avoid confusion. Biochar is further distinguished as hydrochar or pyrochar. Hydrochar is obtained by pyrolysis via hydrothermal carbonization (HTC) in the presence of water and under self-generated pressure at temperatures between 180 °C and 350 °C, whereas pyrochar is the solid product formed under dry pyrolysis conditions at temperatures between 300 °C and 700 °C and higher. If the organic carbon content of the charcoal is above 50%, its atomic H/C ratio is <0.7 and if it derives from sustainable organic resources, it can be considered as biochar according to the European Biochar Certification (EBC, 2019). Formed by both anthropogenic activities and during natural fires, smaller particles of PyC can be transported in aerosols by wind reaching even to Arctic sites.

Combustion and pyrolysis lead to the transformation of organic matter to carbon dioxide (CO₂), carbon monoxide (CO), nitrogen gas (N₂), and volatile organic compounds (VOC) that are released, and the concentration of the organic fraction in the char decreases with heat intensity leading to relative preservation of the mineral phase. Complete combustion removes all organic matter leaving the mineral phase as a white powder commonly referred to as ash. Composition of the ash depends on the mineral content of the feedstock and is the main contributor to the strong alkalinity of many PyCs. In agriculture, it is often used for liming in particular of acid soils and as fertilizer.

Origin of PyC

In natural settings, vegetation fires are the main sources of PyC in soils. Fires have affected the Earth for at least 325 million years, thus fire occurred long before recent soils developed, and the respective PyC residues or markers can still be found in ancient sediments.

Most of the charred residues accumulating on the soil surface were produced by vegetation fires after partial combustion, thus in the presence of oxygen. Here, combustion is the chemical reaction where any fuel is oxidized and heat is produced. Under an unlimited supply of oxygen, clean combustion takes place and turns all organic matter into CO₂ and water. Under those conditions, PyC can only accumulate on the soil if the heat intensity affecting the feedstock was below the threshold needed for complete combustion. However, during burning of wood stems and branches, air supply may become restricted leading to pyrolysis

conditions that considerably increase the temperature needed for a complete degradation of the fuel. Furthermore, underground smoldering fires, occur under oxygen-depleted thus pyrolysis-like conditions.

Air transport of fine particles and volatile compounds of PyC released during a fire via aerosols or as fine particles can affect the health of ecosystems by their deposits on plant leaves and soils. The aerosols or fine particles contribute to increases in temperature, reduce the sunlight reaching the Earth, and modify rainfall patterns. Changing rain patterns can have far-reaching consequences for both ecosystems and human livelihoods, for example by disrupting monsoons, which are critical for agriculture in large parts of Asia and Africa. However, most of the PyC reaches the soil after vegetation fires or as a soil amendment in the case of biochar. Wildfires of medium intensity, in particular, produce large amounts of PyC (Certini, 2005), a considerable portion of which suffers erosion and is transported from terrestrial to aquatic systems either as particles or as dissolved PyC. These can contribute to the organic matter in river, lake or ocean sediments. After having been partially oxidized at the soil surface, the increased solubility of PyC in water allows vertical transport either with the leaching water or adsorbed on soil particles into deeper soil regions where it can accumulate (Velasco-Molina et al., 2016). However, transport within the soil can also be caused by bioturbation. Wagner et al. (2017) suggested that other components of dissolved organic matter may act as mediators in the solubilization of condensed aromatic molecules and serve to increase the solubility of PyC.

The extent of PyC production during the burning of organic matter depends largely on combustion intensity, i.e., fire intensity. Prescribed (controlled) fires and post-harvest fires are initiated at moderate soil moisture and generally have low severity. Fires in grassland with lower fuel loadings usually have ground-level temperatures of $<25^{\circ}\text{C}$, although higher temperatures have been measured. Uncontrolled wildfires in areas with abundant dry fuel can be severe, although the severity can be very heterogeneous due to variation in fuel distribution and other local factors. Intense forest fires can lead to temperatures of at least 1500°C , but soil surface maximum temperatures are usually around $500\text{--}700^{\circ}\text{C}$. Rates of spread are commonly fast (i.e., as much as 7 km h^{-1}). Fast moving fires on grass may be intense in terms of energy release per unit area, but do not transfer the same amounts of heat to mineral soil as do slow-moving fires involving moderate to heavy fuel loads. However, the longer is the duration of the fire, the greater is the belowground damage to ecosystems. With depth, the severity of heating decreases depending on factors such as intensity and duration of heat transfer, heat conductivity of the mineral phase, soil porosity and soil moisture. In general, in dry soils, below-ground temperatures will rise very slowly because they are a very good insulator.

In peat and swamp areas smoldering fires spread at low speed, as low as 0.5 m week^{-1} . Lowering the water table is a considerable hazard because drying the peat creates a significant amount of high-energy fuel. Fires that can burn deep into the peat may even be able to survive several centimeters of rainfall. The respective loss of organic material can be dramatic such that the peat surface sinks clearly with respect to its surroundings.

Methods for the characterization of the chemical structure of PyC

Several models that describe char on a molecular level are reported, but a real understanding of the chemical nature of PyC is still lacking, most probably due to the heterogeneous nature of its constituents and the strong chemical resistance of some that reduces its accessibility to extraction and subsequent analyses. Although HTC, pyrolysis and incomplete combustion result in blackish material with large contents of aromatic C, the chemical reactions involved differ and determine the chemical composition of the final product. In addition, the charring intensity expressed in heat intensity, length of time of thermal treatment, and the nature and composition of the feedstock affect the nature and properties of PyC.

Elemental analysis and Van Krevelen diagrams

A first approach to reveal the chemical structure of PyC represents determination of the elemental composition (contents of carbon, nitrogen, oxygen and hydrogen), which is mainly performed by dry combustion. Techniques that use chemical oxidation such as the Walkley Black method are of limited use since they may miss inert forms of carbon such as highly polyaromatic structures.

The elemental composition of the PyC can be plotted as a Van Krevelen diagram, originally developed for assessing the origin and maturity of kerogen and petroleum. It cross-plots the hydrogen:carbon (H/C) atomic ratio as a function of the oxygen:carbon (O/C) atomic ratio (Fig. 1). The H/C ratio separates compounds according to their degree of saturation, whereas the O/C ratios display the O classes. Specific regions of the Van Krevelen diagram are associated with specific compound classes, such as carbohydrates, lipids, lignin or peat. Following the chemical alteration of biomass compared with heat severity via a Van Krevelen plot, shifts assigned to decarboxylation, dehydration or demethylation can be followed by the location in the plot. Maturation of natural coals or increasing heat intensity during PyC formation is associated with dehydration, condensation and decarboxylation which moves the cross plots to the lower left corner of the diagram. Accordingly, the location of the cross plots provides valuable information about the degree of aromatization and coalification of the PyC.

For soot, atomic H/C ratios of <0.2 were determined, which accord with a highly condensed aromatic network. Graphenic structures have also been confirmed for PyC produced under pyrolysis conditions (without oxygen) at temperatures $>700^{\circ}\text{C}$ (Freitas et al., 1999). However, PyC produced at lower temperatures shows atomic H/C ratios >0.5 . Paneque et al. (2017) and Hoffmann et al. (2019) found atomic H/C ratios of hydrochars between 0.7 and 1.1. Such values demonstrate that, on average, at least every second C is protonated and consequently the chemical structure of such PyC differs greatly from that expected for soot.

Fig. 1 Van Krevelen Plot correlating the atomic H/C and O/C ratios of different feedstocks, hydrochars, pyrochars and chars produced under oxidic conditions. The circles embrace data derived from pyrochars produced within the indicated range of pyrolysis temperature. Data are obtained from Knicker H, et al. (2008) A new conceptual model for the structural properties of char produced during vegetation fires. *Organic Geochemistry* 39(8): 935–939. <https://doi.org/10.1016/j.orggeochem.2008.03.021>. Knicker H (2010) “Black nitrogen”—An important fraction in determining the recalcitrance of charcoal. *Organic Geochemistry* Pergamon. 41(9): 947–950. <https://doi.org/10.1016/j.orggeochem.2010.04.007>. Paneque M, et al. (2017) Hydrothermal carbonization and pyrolysis of sewage sludges: What happen to carbon and nitrogen? *Journal of Analytical and Applied Pyrolysis* 128: 314–323. <https://doi.org/10.1016/j.jaap.2017.09.019>. Hoffmann V, et al. Campos P, et al. (2020) Chemical, physical and morphological properties of biochars produced from agricultural residues: Implications for their use as soil amendment. *Waste Management* 105: 256–267. <https://doi.org/10.1016/j.wasman.2020.02.013>.

The concept of differing chemical structures for soot and charcoal PyC is also supported by the atomic O/C ratios. Soot exhibits typical values of <0.3 , whereas PyC originating from plants and SOM have average atomic O/C ratios of up to 0.5. Such relatively large O concentrations are inconsistent with a large and graphitic network of condensed polyaromatics. They tend to confirm the participation of anhydrosugars, furans, pyranones, and 5 hydroxymethylfurfural (HMF) formed by the thermal alteration of cellulose and other carbohydrates.

Degradative techniques

For a more detailed analysis of the nature of PyC, more sophisticated tools are required. Many of these require solubility of the sample or at least of different fractions. This is rarely the case for PyC and for most of its fractions, degradative pre-treatments based on chemical and thermal degradation with subsequent derivatization of fragments produced have been applied to transform at least part of the material into structures that can be identified.

Gas chromatography and mass spectrometry (GC, MS)

Analytical pyrolysis combined with gas chromatography mass spectrometry (GC/MS) is used because it does not require solvent use or pre-concentration of the sample, and is not excessively time-consuming. However, its application for the analysis of heterogeneous mixtures may result in secondary rearrangements of reactive intermediates which can yield components that were not present in the original sample. Evidently, this can bias the interpretation of the data obtained. Correspondingly, proteins may lose their N-containing functional groups and become heterocyclic structures. Polysaccharides can form levoglucans or furans and pyrans by dehydration. Fatty acids may decarboxylate producing n-alkane or n-alkene pairs of which a small proportion may cycle to alkylbenzenes and alkyl-naphthalenes or lignins may be demethylated. In addition, one must also bear in mind that comparable reactions occur during analytical pyrolysis and PyC formation, which reduces the distinction between the origin of the compounds identified.

A further problem is that only compounds that have not been volatilized during previous PyC formation can be released during analytical pyrolysis. Consequently, compounds of PyC can be identified only if the temperature during analytical pyrolysis is higher than that during PyC formation.

Thermogravimetric analysis with differential scanning calorimetry

Thermogravimetric analysis (TGA) probes the thermal stability of materials and relates it to specific compound classes present in the sample. The sample is heated to high temperatures at a constant rate while monitoring heat-induced weight changes. The mass loss at a certain temperature can be associated with the decomposition of different sorts of OM. By combining TGA with differential scanning calorimetry (DSC) and a pack bed, together with online gas measurement using Fourier-transform infrared (FTIR)

spectroscopy enables the identification of hemicellulose, cellulose, and lignin in biomass together with the gas products from the biomass pyrolysis.

The TGA–DSC is already applied routinely to characterize chemical changes in organic matter fractions of soils and sediments, degraded plant tissue and composts, but has also been used to characterize forms of PyC. Observations using this technique confirmed the idea of PyC as a continuum in terms of thermal stability. Addition of charcoal and soot to soils revealed a strong linear relationship between the amount of added and detected PyC, from which it was concluded that this method may be suitable to quantify thermally stable PyC in soil. Coupling TGA–DSC to an isotope ratio mass spectrometer (IRMS) enables better discrimination of the organic matter and PyC components of different sources and varying thermal stability.

Spectroscopic techniques

Spectroscopic techniques such as infrared (IR) or solid-state nuclear magnetic resonance (NMR) spectroscopy may be applied as alternatives to degradative analytical tools. Infrared measures the interactions of infrared radiation with organic matter and identifies the vibrations of different bonds, whereas NMR takes advantage of the magnetic properties of a nucleus in different chemical and physical environments and probes its interactions with a radio-frequency pulse in a static magnetic field.

Fourier transform infrared spectroscopy

A typical Fourier transform (FT) IR spectrum of PyC reveals adsorption bands around 3400 cm^{-1} assignable to H-bonded O–H stretching vibrations of hydroxyl groups from alcohols, phenols, and organic acids around $2900\text{--}2800\text{ cm}^{-1}$ indicating the presence of CH groups. Absorption at a wavelength of $1700\text{--}1400\text{ cm}^{-1}$ is evidence of aromatic and olefinic C=C vibrations and C=O in amide (I), ketone and quinone groups. A peak around 1680 cm^{-1} , corresponds to carbonyl groups, a band at 1460 cm^{-1} to C–H deformation of CH_3 groups and adsorption at wave number $900\text{--}700\text{ cm}^{-1}$ to aromatic CH. Important advantages of this technique include its low costs, small sample size required and ease of use, but it fails to provide quantitative data. If this is needed, the more expensive but highly sophisticated solid-state NMR spectroscopy is recommended.

Solid-state ^{13}C nuclear magnetic resonance spectroscopy

Most solid-state ^{13}C NMR spectra of PyC are defined by an intense but broad signal assigned to aromatic C (Fig. 2), which distinguishes them from spectra of common soils with no impact of fire or biochar addition. Depending on the carbonization

Fig. 2 Solid-state ^{13}C NMR spectra of pyrogenic C (PyC) from different feedstocks and produced under (a) oxidic conditions and (b) pyrolysis.

Fig. 3 Solid-state ^{13}C NMR spectra of soil organic matter (SOM) in topsoils of Cambisols from Central Spain which were not affected by fire and were taken 11 years after a severe fire event.

degree of the PyC smaller signals attributed to alkyl C are also visible in the spectrum. A more detailed analysis of such spectra often allows the identification of a small shoulder assignable to O-substituted aromatic C (O-aryl C) on the low field side of the peak of aromatic C resonance. In an NMR spectrum of a typical soil such a signal is attributed to phenol C in lignin or tannins (Fig. 3). Those, however, suffer considerable modification during heat treatment at elevated temperatures. Although the contribution of this phenol to the total aromaticity represents an important parameter not only for a better understanding of the chemical structure but also for elucidating the reactivity and adsorption capacity of a biochar, it is rarely considered, most probably because a highly condensed aromatic network is generally assumed.

Solid-state ^{13}C NMR spectra of soil and PyC are commonly acquired with the cross polarization technique. This is based on the transfer of magnetization from the highly abundant ^1H spin system to the rare ^{13}C spins (cross polarization; CP) which are finely detected and quantified. In brief, the time needed for a complete transfer, thus for a full magnetization of the ^{13}C spins depends upon the strength of the interactions or coupling between ^1H and ^{13}C . If ^1H couples strongly with ^{13}C , for example for directly bound ^1H in carbohydrates, the CP is efficient and complete within a short CP time (T_{CH}), whereas a considerable increase of this parameter is expected in condensed polyaromatic structures. This behavior can create a problem because during CP, the ^1H spin system loses energy to the environment (relaxation) and can only partially cross-polarize the ^{13}C . However, if the relaxation is sufficiently long to allow almost complete cross polarization, acquisition parameters can be applied that circumvent biased quantification of such spectra.

To obtain more detailed information about the structure of the aromatic network in PyC, modern solid-state NMR spectroscopy offers special pulse sequences which allow an improved assignment of signal intensity to C groups. One of these is the two-dimensional (2-D) ^1H - ^{13}C heteronuclear correlation (HETCOR) NMR experiment in which ^{13}C and ^1H are correlated through their spin-spin interactions. This allows identification of the connection between specific proton and carbon groups and has also found its way into PyC research contributing to a better understanding of the processes that occur during the formation of PyC.

Alteration of the chemical structure of PyC during heating

Decomposition temperature of major biopolymers

The thermal stability of biomass depends strongly on the reaction medium in which the process is carried out. Under pyrolytic conditions, hemicellulose and cellulose will decompose at lower temperatures than lignin. Hemicellulose decomposes at between 220 °C and 315 °C, followed by cellulose (315–400 °C). The preferential loss of carbohydrates is also indicated by an increase of $\delta^{13}\text{C}/^{12}\text{C}$ of PyC relative to the feedstock (1–2‰) attributable to loss of the isotopically heavier cellulose.

The decomposition of lignin occurs over a temperature range from 160 °C to 900 °C. Sharma et al. (2004) reported that approximately 40% and 60% were volatilized at 450 °C and 750 °C, respectively. Condensation reactions among the volatile products, leading to the formation of coke, were absent under the pyrolysis conditions used. Repeating the experiment under oxidic conditions led to comparable char yields at temperatures up to 350 °C, but at 550 °C only 20% was sequestered from complete combustion that remained as char.

Experiments during which lignin, cellulose and grass residues were burnt (under oxidic conditions) at 350 °C for 8 min yielded 67%, 11% and 34% recovery, respectively, of the initial weight as solid residue (Knicker et al., 2008). Increasing the temperature to 450 °C decreased the yield to 23%, 3% and 18%, respectively (Knicker, 2010). After pyrolysis of cellulose at 350 °C for 1 h, 33% of the total weight was recovered (Knicker et al., 2021), indicating that under oxidic and anoxic conditions different reactions are responsible for the thermal degradation.

With casein as a reference for proteins and peptides in PyC precursors, burning in an oxic environment at 350 °C and 450 °C for 4 min resulted in a recovery of PyC of 48% and 23%, respectively (Knicker et al., 2008). Applying TGA showed that thermal degradation of casein follows a complex mechanism with chemical degradation starting at 176 °C. The main degradation was observed between 248 °C and 634 °C leaving a stable residue of 20% of the initial sample (Mocanu et al., 2012).

During HTC, the degradation and depolymerization of biomass occur at considerably lower temperatures than during dry pyrolysis. Accordingly, hemicellulose and cellulose decompose around 160–180 °C, whereas most of the lignin remains stable until near or above the critical point of water. With the presence of hot compressed water in the HTC process, the degradation of biomass is primarily initiated by hydrolysis, resulting in cleavage of ether and ester bonds.

Further factors that have to be considered if heating temperature and organic matter degradation are correlated, are moisture of the feedstock and heating time. Burning moist feedstock is associated with heavy smoke that condenses to tar and acidic residues on cold surfaces. It produces less heat and leads to incomplete combustion. Thus, considerably higher temperatures than those reported for complete combustion from laboratory experiments are needed to allow charring of fresh wood or moist litter layers. Furthermore, heating time plays an important role, since chemical reactions can only occur if the respective activation energy has been reached and even surpassed. This requires that the heat needed has completely and homogeneously penetrated through the heated feedstock. Campos et al. (2020) showed that pyrolysis of different feedstocks at 500 °C for 30 min was not long enough to remove alkyl C; it required heating for 1 h for an almost complete removal of such a structure. Increasing pyrolysis time to 2 and 4 h, however, did not cause major additional chemical alterations. Charring grass residues under oxic conditions at 350 °C, a burning time of 75 s, was needed to initiate noticeable heat-induced alteration of the chemical composition of solid residue, although weight losses were identified with less heating time (Knicker et al., 1996). With this in mind, the discrepancy between the relation between temperature and chemical changes of organic matter during wildfires and organic matter pyrolyzed or combusted in laboratory experiment as described by Santín et al. (2016) can be explained. They observed that under typical wildfire conditions substantial chemical changes in the organic matter of the forest floor occurred at temperatures >600–700 °C rather than 30–400 °C commonly assumed from laboratory experiments. Charred organic residues were still detected after the fire reached temperatures of 950 °C, a temperature at which under oxic conditions all organic matter should have experienced complete combustion. However, the rate of spread of the observed fire was around 6–7 m min⁻¹ resulting in average heating durations of the forest floor of 180 s at 300 °C, 81 s at 500 °C and 21 s at 700 °C. Such short heating times would certainly not allow efficient heat and energy penetration below the outer surface of the forest floor.

Chemical structure of PyC

Most of what we know about thermal decomposition of biomass comes from experimental studies carried out under pyrolytic conditions. A few studies only considered thermal degradation in the presence of oxygen.

Older models describing the chemical nature of PyC assume a polycondensed aromatic network in which the cluster size increases with temperature. Ultimately, micrographitic sheets are formed. However, newer research, in particular in fuel and material sciences, confirmed that such a model is oversimplified if a description of PyC is intended.

Transformation of cellulose and hemicellulose during heat treatment

The solid-state ¹³C NMR spectra in Fig. 2 indicate that the organic composition of PyC from different feedstocks produced under different conditions can vary considerably, although all spectra reveal elevated aromatic C concentration if compared to the original feedstock. Thermal decomposition starts with dehydration and condensation reactions which accords with decreasing atomic H/C and O/C ratios. At mild temperatures, this affects mainly carbohydrates and leads to their depolymerization and fragmentation, and also the formation of volatile products together with char. Major products are levoglucosan and furanose derivatives, furfural, HMF and hydroxybenzene. In an ¹³C NMR spectrum, this can be verified through the relative decrease of the O-alkyl C signal intensity by the concomitant increase of signal intensity in the aryl C and alkyl C regions. Based on this observation the aromatic C/alkyl C ratio was suggested as an index to describe the degree of charring of vegetation residues and SOM. However, here one has to keep in mind that feedstocks with a large content of lipids or proteins will shift this ratio toward higher alkyl contents because the alkyl chain of these biomolecules has higher thermal stability than carbohydrates.

As indicated by X-ray diffraction, heating of biomass goes together with a decrease in crystallinity, and the augmentation of amorphous structures by the destruction of hydrogen bonds and cleavage of molecular chains. Above 550 °C graphene sheets are formed, although the overall structure remains substantially disordered. With increasing temperature progressive stacking of the graphene sheets and lateral growth of graphene planes resulting in the formation of crystallites were deduced. These observations accord with those of Tang and Bacon (1964) who reported a large weight loss and breakdown of crystalline structures after pyrolysis of cellulose at 400 °C, which was associated with the thermal scission of 1–4 glycosidic linkages and dehydration reactions. They identified aliphatic aldehydes, ketones and acids which seemed to be an integral stable part of the solid char at these temperatures. With higher temperatures their contribution declined due to thermal decarbonylation. There is evidence that most of the aromatic structures of the cellulose char pyrolyzed at 350 °C can be assigned to benzofuran-like units rather than to polyaromatic clusters. Their contribution decreases with pyrolysis temperature probably because of bond cleavage and conversion of furan groups to hydroxyl-substituted aromatic C. However, Fig. 2 shows that different reactions occur during thermal degradation of cellulose under oxic and anoxic conditions from the missing signals assignable to aliphatic aldehydes, ketones and acids in the spectrum of cellulose PyC produced under oxic conditions.

The different thermal stability of hemicellulose and cellulose shows that the mechanism involved in their thermal degradation also differ. Falco et al. (2011) suggested that glucose units are dehydrated to HMF that condense to a polyfuranic network and subsequently condensate to polycondensed aromatic units with occasional substitution of aromatic rim carbon.

Heat-induced alteration of lignin

Lignin is a polymer of phenylpropane units containing three different aromatic ring substitution patterns: p-hydroxyphenyl, guaiacyl (4-hydroxy-3-methoxyphenyl), and syringyl (3,5-dimethoxy-4-hydroxyphenyl), depending on the wood species. Its thermal degradation starts at a higher temperature than hemicellulose and cellulose, therefore, its solid residue is relatively enriched in plant-derived PyC formed at temperatures $>350^{\circ}\text{C}$.

The first change in the thermally induced alteration of the solid residue is comparable to the pyrolysis of cellulose and concerns the loss of O-alkyl C, which is best explained with dehydroxylation and partial loss of propanyl side chains. These reactions are the main cause of the weight loss both during pyrolysis and partial combustion, although some removal of aromatic C occurs. The relative increase of the aromatic C during thermal treatment of lignin is different from that of cellulose and is caused by selective preservation of the lignin-derived aromatic structures rather than by their neoformation both under oxic and pyrolytic conditions (Sharma et al., 2004). Knicker et al. (2008) concluded that demethylation leaving hydroxylated aryl C rather than demethoxylation occurs at temperatures up to 350°C . For this char, they revealed that at least every second aryl C is protonated which corresponds to small cluster units such as anthracene or benzanthracene. Higher temperatures, however, decreased the contribution of phenol C concomitantly with alkyl C, leaving a small signal attributed to terminal methyl groups. Sharma et al. (2004) suggested that the weight loss observed during the heating of lignin from 400°C to 600°C is caused by the elimination of phenol C which is likely to result in the condensation of smaller aromatic rings into larger polycondensed aromatic networks.

Fate of Lipids during heating

Prolonged charring reduces the average chain length of n-alkanes and shifts the characteristic odd/even predominance of fresh plants toward a balanced odd/even distribution. Unsaturated fatty acids are more affected by heat than their saturated counterparts. Although it was suggested that the composition of aliphatic and aromatic hydrocarbons of fire-affected recent and fossil soils offers specific indicators, "fingerprints," for the diagnosis of vegetation burning and burning conditions, one has to consider that their microbial decomposition and biosynthesis within a soil matrix can rapidly modify n-alkanes and fatty acid series. Thus, their instability against biodegradation may hamper the identification of charcoal residues in such environments.

Formation of black nitrogen

Originally, black nitrogen (BN) was not a common concept included in the description of PyOM, since most PyOM was expected to derive from wood residues commonly containing negligible amounts of nitrogen (N). However, charring protein-rich plant residues often leads to decreasing C/N ratios which is best interpreted by a selective enrichment of N-containing compounds. With the introduction of solid-state ^{15}N NMR spectroscopy as a routine analytical tool for the characterization of soil organic matter, a door opened that allowed a more detailed analysis of the N-functionality of charred residues and coal.

Applying this technique revealed that heteroaromatic N represents an integral part of the aromatic structure of PyC. Based on this, the term BN was introduced with the intention to enhance attention that aside from pure organic C structures, PyOM can contain organic N moieties if it derives from N-containing feedstock. The heat-resistant N compounds were identified as pyrrole or indole-type N with a minor contribution of pyridine N derives mainly from proteins and peptides that decompose thermally by systematic and random depolymerization reactions. Note that many proteins have higher thermal recalcitrance than cellulose.

Another important reaction that occurs during charring of biomaterial is the Maillard reaction. During this process, ammonia or free amino groups of amino acids and amino sugars react with carbonyl groups of sugars to form Schiff bases that subsequently undergo rearrangements via Amadori compounds to produce dark-colored melanoidins. The major compounds found after pyrolysis of four Amadori compounds derived from glucose and that reacted with asparagine, valine, leucine and threonine were ketones, aldehydes, pyridines, pyrazines, pyrroles and carboxylic acids.

Taking the narrow atomic C/N ratios for pyrrole ($\text{C/N} = 4$), pyridine ($\text{C/N} = 5$), and carbazole ($\text{C/N} = 12$), the approximate contribution of such heterocyclic compounds to PyOM can be estimated from the C/N ratio of PyOM. In particular for N-rich plant residues, BN can comprise a considerable fraction of the charred residue. After having been incorporated into soils, the bound N will become part of the refractory N pool which is not directly available for biomass production. The expected high biochemical recalcitrance of this nitrogen initiated the idea that N-rich PyC could be used as slow-release fertilizer.

Conceptual model for the chemical structure of PyC

According to results obtained from charring experiments and reports from the pyrolysis literature, PyCs are considerably heterogeneous which will determine their physical properties and behavior in soil systems. Based on this it was proposed to replace the former model of highly polycondensed aromatic structures with a concept that reflects better the strong variability of feedstock and production conditions. According to this concept (Knicker et al., 2008), PyC is a heterogeneous mixture of thermally altered biomolecules. The degree of their alteration depends upon the severity of the heat treatment and the chemistry and heating conditions. In particular, in plant-derived material heated to 400°C furans and ketones and pyrroles occur together with sparsely altered lignin residues and some lipids. At this stage, the degree of condensation of the aromatic structures is relatively low and does not exceed an average aromatic cluster size of six rings. Note that for cellulose, in particular, different chemical reactions occur

under oxic and pyrolysis conditions. Intensively charred material (>500–600 °C) reflects a greater degree of condensation and has an entirely aromatic structure with little alkyl C residues. With respect to elemental analysis N, O and probably also S (sulfur) substitutions are common features of the charring products.

Effect of PyC on soil properties

Quality of SOM and soil color

Incorporation of PyC into soils increases the concentration of aromatic C and N and to a lower extent that of alkyl C, which alters not only the quantity but also the quality of SOM (Fig. 3).

During natural humification, acidic functional groups are formed, whereas the addition of PyC decreases the relative contribution of O-groups and increases hydrophobicity. The latter may affect soil water distribution and adsorption properties. After wildfires, the content of water-soluble organic compounds declines although there is a gradual restoration over time. A further major alteration of soil properties induced by the addition of PyC is darkening of the soil, which is commonly related to the increasing aromaticity. However, there was no correlation between the aromatic C content of model chars and darkness (Knicker, 2011) indicating that the latter is also determined by the specific structure of the aromatic network. Other factors such as calcium carbonate content, soil texture and interaction with metals may contribute to the darkness of a soil. Long-term effects of PyC addition can be evaluated by characterizing soils around former charcoal kilns. In addition to larger SOM contents, greater aromaticity and a lower percentage of dissolved organic matter, the large and continuous input of PyC into the soils surrounding such ancient kilns resulted in higher pH values, cation exchange capacity and nutrient contents than in comparable soils that were unaffected by the former charcoal production. Based on such observations, it was suggested that the natural weathering and biochemical reworking of charcoal in soils, together with ash input, is sufficient to generate fertile and resilient soils with unusual SOM and properties commonly associated with the high fertility and C sequestration potential of the typical Terra preta de Índios.

Soil pH

Loss of CO₂ and volatile organic compounds during partial combustion and pyrolysis of vegetal feedstocks results in an accumulation of mineral matter with a large content of cations causing an increase of pH to alkaline values, together with large electrical conductivity. This provides not only nutrients previously immobilized in the growing plant to the soils but can also contribute to an increase of the soil pH; although significant effects are only expected for PyC produced at temperatures >450 °C. In contrast to soils with frequent inputs of PyC, however, this effect, known as the liming effect, does not persist on a long-term scale in soils occasionally affected by a wildfire. Here, the nutrients are rapidly used for the build-up of the re-growing vegetation or they are lost by leaching or removal of PyC by erosion. In particular, on steeply sloping soils, the latter represents a major danger for nutrient depletion of fire-affected sites. The low density and high hydrophobicity of PyC and the fact that it is accumulating on the soil surface make this material particularly susceptible to transport by water flows following heavy rains into catchments, river systems and eventually into oceans. This will not only remove nutrients but will also dislocate considerable amounts of organic carbon associated with PyC.

Nitrogen and phosphorus availability for plants

Production of PyC is accompanied by N losses to the atmosphere, which in the case of vegetation fires is lost from the respective ecosystem. On the other hand, ammonium as a direct product of combustion can accumulate in the burnt soil. Nitrate on the other hand is not directly formed by the fire but derives from the transformation of ammonium (nitrification). In undisturbed soils, the use of ammonium by nitrifiers is in strong competition with the vegetation. Destruction of the vegetation and combustion of the allelopathic compounds, such as terpenes and phenolics promotes the increase of nitrifiers and the transformation of available ammonium to nitrate. However, without any potential plant uptake nitrate will be lost from the ecosystem either by denitrification or leaching. If prompt recolonization by plants does not occur, this loss can have subsequent effects on plant succession and ecosystem restoration.

A considerable fraction of the N of feedstock is sequestered as BN, which can be mobilized and subsequently used by microorganisms and plants for build-up of their biomass. Its rate of incorporation into microbial and plant biomass is considerably less than that from inorganic N or unburned organic N. In particular, in fire-affected areas, the lower bioavailability of N in BN prevents complete N-loss from the fire-affected soil layer by leaching after the first post-fire rains. Therefore, BN accumulation after fires may play a more important role in the recovery of a fire-affected ecosystem than formerly thought.

A comparable conclusion may be drawn for phosphorous (P) which accumulates in the solid residue after heating of vegetal feedstocks. Burning liberates organic P from SOM as plant-available orthophosphate which is not lost by volatilization and can accumulate on the soil surface. The bioavailability of this P may be promoted by the liming effect since the greatest P bioavailability is around pH 6.5. However, binding of P to Ca-minerals in neutral and alkaline soils and to Al (aluminum), Fe (iron), and Mn (manganese) in acid environments cancels out the positive nutrient effect. Similar to N, heating of biomass leads to a relative

enrichment of P in the PyC. Its plant availability declines with reaction temperature (Dai et al., 2016). After PyC has been amended to soil covered with plants, part of the P that was immobilized into the PyC turns into mobile plant-available forms (Dai et al., 2016). Future research needs to show if this is due to processes initiated by development of the root and vegetative system of the plants or by microbial activities in the rhizosphere.

Porosity

The destruction of cell structure and the chemical alteration of biomolecules during heating of vegetal biomass increases the porosity during PyC formation. Pore size and distribution in PyC represent an important factor defining its ecological role in soils. In addition to providing niches for microbes, adsorption sites for nutrients, and also metals, this property can have a major positive impact on the water holding capacity of the amended soil.

Measuring the porosity of PyC is challenging because pore size ranges over at least five orders of magnitude, from sub-nanometer sizes to pores of tens of micrometers that remain from partially destroyed cellular structures. Macropores and mesopores can be revealed by microscopic techniques such as X-ray microtomographic imaging or scanning electron microscopy.

Smaller pores in the range of nm (micropores and mesopores) are commonly analyzed by gas adsorption techniques accompanied by the Brunauer–Emmett–Teller (BET) modeling to determine the specific surface area (SSA). However, pore space analysis based on these methods and models is limited to pores smaller than 300 nm, which gives little information about its water holding properties once introduced into soils. The most common probe for the determination of SSA is N₂ (at 77 K). However, its value for PyC is questionable because of deformation and swelling processes during adsorption and the fact that N₂ adsorption is severely restricted by diffusion limitation in narrow micropores <0.7 nm. Alternatively, CO₂ adsorption is applied for the characterization of pores <2 nm. Mercury porosimetry can probe pores from a few nanometers to a few hundred micrometers, thus it can detect more of the biochar pore volume than gas adsorption. Apart from safety issues, however, the drawbacks of this technique include the risk of crushing the sample with the high pressures required for analysis.

Identification and quantification of PyC in soils

The chemical composition of PyC does not represent a single structure but a wide range of thermally altered materials, therefore, its quantification in soil is challenging. This is particularly so if the quantification includes PyC produced at low temperatures since their properties can overlap with those of uncharred SOM.

Currently, optical, thermal, chemical and photo-oxidation approaches, and also spectroscopic and molecular marker methods are applied for the identification and quantification of charcoal. Each of these techniques relies on operational definitions and covers different regions within the combustion continuum.

Visual or microscopic techniques identify charcoal pieces visually and quantify their amount by subsequent particle counting or physical separation with weighing. This method, however, misses soot and charcoal degradation products. Physical techniques are mostly non-destructive and separate PyC from soil by differences in density or size.

Chemical and photo oxidation, and also thermal methods rely on the refractory nature of PyC, assuming that the latter is selectively enriched whereas the more labile unburned material is destroyed. The widely used technique of chemo-thermal oxidation was calibrated for soot and excludes the identification of PyC at <850 °C. Alternatively, TGA–DSC allows scanning over a wide range of temperatures and thus can provide information about the entire PyC continuum. Assuming that PyC is systematically more stable than uncharred SOM, the first can be distinguished from the latter by a typical thermal signature. However, only slightly charred residues produced below the degradation temperature of lignin may still be underestimated.

Chemical oxidation with peroxide also induces substantial degradation of PyC. Alternatively, oxidation with dichromate is used to separate labile organic matter from highly condensed PyC. Grass and wood are efficiently degraded after 4–6 h, but paraffin structures from plant waxes survive even harsher oxidation scenarios. A considerable part of those structures is removed by subsequent Soxhlet extraction, indicating that their persistence is due to their hydrophobic nature rather than an inherent chemical recalcitrance caused by charring. Persistence of paraffin structures has also been reported in residues after dichromate treatment of some Australian Mollisols and Oxisols (Krull et al., 2006), in sediment samples (De La Rosa et al., 2008) and a peat humic acid oxidized with nitric acid (Simpson and Hatcher, 2004). Consequently, the resistance of such structures to strong acids can be described as a common feature, which can bias PyC quantification with techniques based on chemical oxidation in particular if soils with higher lipid contents are analyzed. A further drawback of this method is that aged, thus carboxylated PyC, can be chemically oxidized and therefore will escape identification by such methods.

Biomarker essays are also destructive and rely on the identification of typical charring products as molecular biomarkers such as benzenepolycarboxylic acids (BPCAs) released after oxidation with nitric acid or levoglucans which are a typical pyrolysis product of cellulose. The latter is used for identification rather than quantification. The BPCAs method is also applied for quantification but it is highly sensitive to operating conditions and to the factor used to convert BPCA yields into PyC amounts. The less condensed fraction of chars is expected to be completely decomposed by the strong oxidative attack, whereas the most refractory, graphitized forms of PyC may resist digestion preceding BPCA analysis. Further, BPCAs derive from C in larger aromatic clusters, which are not major constituents in plant-derived PyC and coals up to the bituminous maturation stage.

Spectroscopic techniques such as X-ray diffraction, FTIR or NMR spectroscopy are non-destructive but are hampered by the difficulty of unbiasedly distinguishing signals from PyC from those of natural SOM. To overcome this problem, one seeks to identify specific spectroscopic patterns that are typical for PyC and enable its identification and quantification within the heterogeneous mixture of SOM.

Degradation pattern of PyC in soils

For a long time, the paradigm that PyC represents an inert and environmentally recalcitrant form of organic carbon was well accepted. Residence times of thousands of years were generally assumed. Table 1 gives a short overview about mean residence times of PyC in soils (Knicker, 2011).

However, this view has changed over the past few decades with the knowledge that PyC comprises a range of materials with different biochemical stability and degradation pathways. Biochemical stability of PyC is commonly related to the temperature during its production and the aromaticity obtained. In addition to the chemical properties of the PyC, the degradability of such residues depends on the environmental conditions under which degradation takes place. These can vary considerably. Oxidic conditions may favor degradation over anoxic conditions as PyC abundance decreases in oxidic compared with anoxic marine sediments (Masiello and Druffel, 2003). Warm and humid conditions are likely to enhance microbial degradation. Interaction with minerals on the other hand may hinder the ability of microorganisms to access and decompose PyC residues. Additional labile litter input may induce priming and stimulate PyC degradation, whereas the addition of N can decrease PyC cycling.

Under the alkaline conditions of calcaric soils or ash layers, chemically mediated physical interactions can result in fragmentation of the charcoal which enables its transport by wind and water both vertically to deeper soil regions and horizontally by erosion. Cheng et al. (2006) suggested abiotic processes such as chemisorption of oxygen on unsaturated ring carbon with its subsequent oxidation play a major role in the PyC degradation process. There is evidence for microbial degradation although not much is known about the participating organisms. Organisms that degrade lignin are most probably involved. The use of solid-state ^{13}C NMR spectroscopy to study the chemical alteration during biotic degradation of plant chars showed that within 2 months the chemical structure of the remaining PyC was strongly modified. This included the formation of O-containing functional groups and the loss of aryl C structures by mineralization and conversion to other carbon groups, mostly carboxylic C (Hilscher and Knicker, 2011). A two-step mechanism was suggested: the first step involves the formation of catechol-like structures from microbially accessible aryl rings, and second, the oxygenated O-aryl rings are cleaved, which increases the amount of carboxyl and carbonyl C. This will not only increase the accessibility of the ring system for further microbial degradation but also enhance its solubility, facilitating subsequent transport within the soil column as observed in soils of the Brazilian Cerrado (Velasco-Molina et al., 2016) or in aquatic systems (Wagner et al., 2017). Modeling the degradability of PyC in aquatic systems revealed comparable bioavailability to dissolved organic matter (DOM). It was concluded that PyC may be actively transformed within the river corridor.

Table 1 Mean residence times of selected PyC published in the literature and the method of their determination.

Material and production condition	Degradation condition and its determination	Mean residence time	Literature
Rye-grass PyC mixed with soil from the B horizon of a Cambisol (350 °C, 4 min, oxidic)	Laboratory incubation (48 days)	19 years	Hilscher et al. (2009)
Pine wood PyC mixed with material from the B horizon of a Cambisol (350 °C, 4 min, oxidic)	Laboratory incubation (48 days)	56 years	Hilscher et al. (2009)
Straw PyC mixed with sand (350 °C, 2 h, pyrolysis)	Laboratory incubation (60 days)	39 years	Hamer et al. (2004)
Oak wood PyC mixed with sand (800 °C, 20–24 h, pyrolysis)	Laboratory incubation (60 days)	76 years	Hamer et al. (2004)
Sapwood PyC mixed with sand (200–350 °C, 24–72 h, pyrolysis)	Laboratory incubation (120 days)	<2% of total C after 120 days	Baldock and Smernik (2002)
Natural PyC in soils (Savannah)	Natural soils, isotopic ratio determination	<100 years (half-life time)	Bird et al. (1999)
PyC containing light fraction	long-term field trial	21–23.4 years	Murage et al. (2007)
^{14}C -labeled rye grass PyC mixed with material from the Ap horizon of an Haplic Luvisol (13 h, 400 °C, pyrolysis)	Laboratory incubation (1181 days)	200 years	Kuzyakov et al. (2009)
^{14}C -labeled rye grass PyC (13 h, 400 °C, pyrolysis)	Extrapolation from laboratory data to natural soils	2000 years	Kuzyakov et al. (2009)
PyC in Chernozems	Natural soils, isotopic ratio determination	1160–5040 years	Schmidt et al. (2002)
PyC in sediments	Chronosequence, chemical oxidation	2400–13,900 years	Masiello and Druffel (1998)

Modified from Knicker H (2011) Pyrogenic organic matter in soil: Its origin and occurrence, its chemistry and survival in soil environments. *Quaternary International* 243(2): 251–263. <https://doi.org/10.1016/j.quaint.2011.02.037>.

Preservation of PyC in soils

Pyrogenic carbon is one of the most resistant forms of reduced organic matter and comprises a major proportion of the slow-cycling carbon pools in terrestrial systems and aquatic sediments. In some fire-affected surface soils, the typical PyC pattern of the SOM remains visible for centuries. In others, however, the pattern is lost after short recovery times either because it is masked by the input of fresh litter or by the loss of PyC due to degradation or erosion. To explain these divergent results a concept was developed to explain, at least in part, the dependence of PyC survival on environmental conditions.

According to the simplified concept shown in Fig. 4, after vegetation fires, a considerable part of the aboveground vegetation is affected or destroyed (1). The PyC formed accumulates on the soil surface (2) and enters the SOM (3) giving it the typical PyC pattern with high aromaticity and hydrophobicity. The extent of this pattern depends upon the severity of the fire and the type of vegetation cover. Increased fire intensity decreases the amount of produced charred residues. Less and finer PyC is expected to accumulate after burning of grassland than after forest fires.

Vegetation fires increase the SOM pool not only by the production of PyC but also by the augmentation of decaying fire-affected but non-combusted above-ground vegetation and roots of dead vegetation (4). Additional fresh litter input is expected from the recovering vegetation (5) which takes advantage of the liming effect and accumulation of plant-available P and N. This can lead to the situation where the amount of SOM developed from this input may exceed the PyC content leading to “masking” (I) of the former PyC pattern (6), although the PyC contents may have changed only slightly. Evidently, increased litter production goes together with an increase of the organic matter content of the soil.

If the newly produced plant biomass is constantly removed which is the case for burned agricultural soils, the PyC is selectively enriched (II) in the soil (7). Management of such soils with frequent post-harvest burning will increase PyC concentration with SOM formed from decaying roots and harvest residues.

Under the oxic conditions of the soil surface, microbial reworking of the PyC (8) or even mineralization (9) starts to leave residues with increased contents of carboxylic functional groups. These groups increase the water solubility of the PyC residues and their adsorption capacity to soil minerals. The latter (10) may increase their stability against further microbial attack, their physical removal into aggregates or their translocation via leaching with clay minerals into dark illuvial horizons with PyC accumulation (11). Alternatively, transport may occur with leaching soil water (12). Here, different conditions such as changes in the soil pH or mineralogy can support immobilization of the dissolved PyC. Oxygen depletion deeper in the soil reduces the biodegradability of transported PyC (13), and compared to sediments the residues are selectively preserved and can survive for decades and even millennia.

Fig. 4 Concept of the fate of pyrogenic Carbon (PyC) in different soil environments. Modified and adapted from Knicker H (2011) Pyrogenic organic matter in soil: Its origin and occurrence, its chemistry and survival in soil environments. *Quaternary International* 243(2): 251–263. <https://doi.org/10.1016/j.quaint.2011.02.037>.

Although its chemical nature differs from that of SOM, in soils, the survival of PyC in soils is determined by similar factors to those of SOM that have been unaffected by fire. Similar to fire-unaffected and humified (stabilized) SOM with residence times of several thousand years, PyC is involved in pedogenic processes. Thus, PyC input by wildfires or human activity of Neolithic and earlier times has contributed to the formation of soils with typical features (i.e., some Chernozems, black illuvial horizon in fire-prone regions, Terra Preta de Índios, soils around ancient kilns and black soils at archeological sites). Consequently, one has to be aware that using fire and PyC amendment as agricultural practices can alter soil environments and properties not only in the short term but also on a long-term scale.

Conclusion

Apart from its impact on soil properties, PyC represents an important contributor to the slow pool of SOM. As such it plays an important role as a C sink within the global elemental cycles. There is increasing awareness that although high aromaticity is certainly a common feature of most PyC, it cannot necessarily be assumed that the chemical nature of the aromatic structures of PyC with different origins is comparable. It should rather be seen as a continuum of thermally altered biomolecules. The degree of these alterations depends on the heat severity, heating conditions (oxic, pyrolysis) and nature of the feedstock. A paradigm shift occurred with respect to the biochemical recalcitrance of PyC that there are microorganisms that can attack and degrade highly aromatic structures. Consequently, the recalcitrance of PyC depends not only on its chemical structure but relies also on soil conditions. Under conditions that support microbial and fungal activity, PyC can be oxidized and eventually mineralized, whereas conditions in dry (i.e., deserts) or oxygen-depleted environments (sediments, deep soils) lead to its preservation and accumulation. Note that partial oxidation of PyC enables its interaction with minerals and its transport as dissolved pyrogenic matter either vertically within the soils or horizontally with superficial waters. Little is still known about the nature of the latter, although it represents a considerable source of PyC in aquatic systems.

This shift of views increased the awareness that there is neither a common structure nor a common behavior that applies to all PyC. This heterogeneity affects not only the predictability of global carbon cycling models that assign PyC to a single stable pool, but also the reliability of methods developed for the identification and quantification of this material by biomarkers, chemical or thermal stability. Thus, there is an urgent need to improve our understanding of the relationship between the structure of PyC and its chemical, physical or biochemical stability. In addition, its thermal resistance has to be considered in particular in environments with frequent fire events. This knowledge will not only increase our general understanding of PyC and its ecological role but will also enable better prediction of the amount and distribution of this material in soils, rivers, oceans and sediments. However, this also requires that analytical tools are developed that can separately determine the proportion and turnover rates of labile, assimilable and stable components of PyC.

Abstract

Fires affect many landscapes whether ignited by lightning or humans. They can affect soil physical, chemical and biological characteristics directly through heating and combustion, or indirectly through modified biological, pedological and hydrological processes after the fire. Direct effects include changes in organic matter, nutrients, biota, water repellency, aggregate stability, and an increased susceptibility to erosion. Indirect effects arise from incorporation of ash and from changes in vegetation cover, the water balance, organic matter inputs or protection from erosion. These effects can last from months to years and, in fire-adapted ecosystems, fire can be considered a key factor in soil formation.

Key points

- Fire effects on soils are highly variable, from negligible to long-lasting. Fire can be a key soil forming factor.
- Fire impacts on soils are both direct, from heating, and indirect, by, for example, ash addition or changes in vegetation cover.
- Fire impacts on soils include changes in their physical (e.g., stability, water repellency), chemical (e.g., pH, organic matter and nutrient contents) and biological (e.g., microbial activity and composition) properties.

Introduction

Vegetation fires (i.e., landscape fires including wildfires and fires ignited for land management purposes) currently burn over 3–5 million km² every year, which corresponds to approximately 4% of Earth's vegetated land surface—roughly the size of Europe (Jones et al., 2019). They have occurred naturally for over 420 million years and humans have used fires to modify the landscape for over 125,000 years (Santín and Doerr, 2016; MacDonald et al., 2021; Roebroeks et al., 2021). Fire can modify physical, chemical and biological characteristics of soils (Fig. 1). This can occur directly through soil heating from the burning of the vegetation, litter and woody debris, and the combustion of soil organic matter itself, or indirectly through modified landscape processes in the post-fire period. Indirect effects mostly arise from the change in vegetation cover, for example, alterations in the water balance, amount and type of organic matter inputs or protection from erosion. Depending on the severity¹ of the fire, these effects can last for

¹Fire severity is a broad term used to describe the degree to which an area has been altered directly by a fire (i.e., burn severity). It most commonly concerns the degree of vegetation destruction. To describe the effect of fire on soil, the term soil burn severity is commonly used (Keeley, 2009).

as little as a few months to many years and can be permanent where temperatures reached result in the modification of soil minerals or where fire leads to land cover changes. In fire-adapted ecosystems fire can be considered as a key factor in soil formation (Certini, 2014).

Fire, combustion and soil heating

Whilst the temperature at the hottest part of a flame in a vegetation fire can exceed $>1000^{\circ}\text{C}$, most of the thermal energy released by the flaming combustion process is directed upwards with only a small proportion available to heat the soil. Thus, the intensity of a fire (i.e., the rate of energy release per meter of flaming front expressed in kW m^{-1}), which is broadly related to the length of the flames, is not necessarily related to the impacts of a fire on soil. For example, a fast-moving intense fire with several meter-long flames rapidly consuming most of the aboveground vegetation may only lead to limited heating of the soil (Stoof et al., 2013), whereas a slow-moving low-intensity fire with small flames (i.e., a long residence time) consuming ground fuels (such as a thick litter layer) can lead to much greater soil heating (Hartford and Frandsen, 1992) (Fig. 1).

In addition, soils are poor conductors of heat due to their porous structure. Dry soils have a thermal conductivity typically below $0.5 \text{ W m}^{-1} \text{ K}^{-1}$, which is low compared to, e.g., amorphous quartz ($>1 \text{ W m}^{-1} \text{ K}^{-1}$) or steel ($>16 \text{ W m}^{-1} \text{ K}^{-1}$). Thermal conductivity increases with soil moisture; however, a substantial amount of energy is used to evaporate this moisture and only once this is driven off can the soil temperature exceed $>100^{\circ}\text{C}$ (Campbell et al., 1994). During flaming fires that consume litter and aboveground vegetation, there is therefore typically a steep temperature gradient in the soil profile with soil a few centimeters below the surface experiencing little if any heating. The highest temperatures and deepest heat penetration typically occur under wood pile burns or smoldering logs. Broad temperature ranges typically reached in mineral surface soils for different types of fires are given in Fig. 1. In relating the impact of a specific temperature on soil characteristics, it is important to consider that it is not only the maximum temperature reached that is important, but also the duration of heating (i.e., the residence time). Temperature thresholds at which changes in soils occur have often been established using prolonged heating (tens of minutes) in laboratory settings, whereas the heat peaks in wildfires often last only seconds (Fig. 2). In general, slow-moving wildfires where large amounts of ground fuel are entirely consumed and deep heat penetration occurs often have the greatest impact on soil. In contrast, fast moving wildfires in low fuel vegetation (e.g., grasses) or prescribed burns carried out at higher soil and fuel moisture contents and where the ground fuel may be only partially consumed have little if any direct effect on the soil (Meira-Castro et al., 2015; Santín and Doerr, 2016).

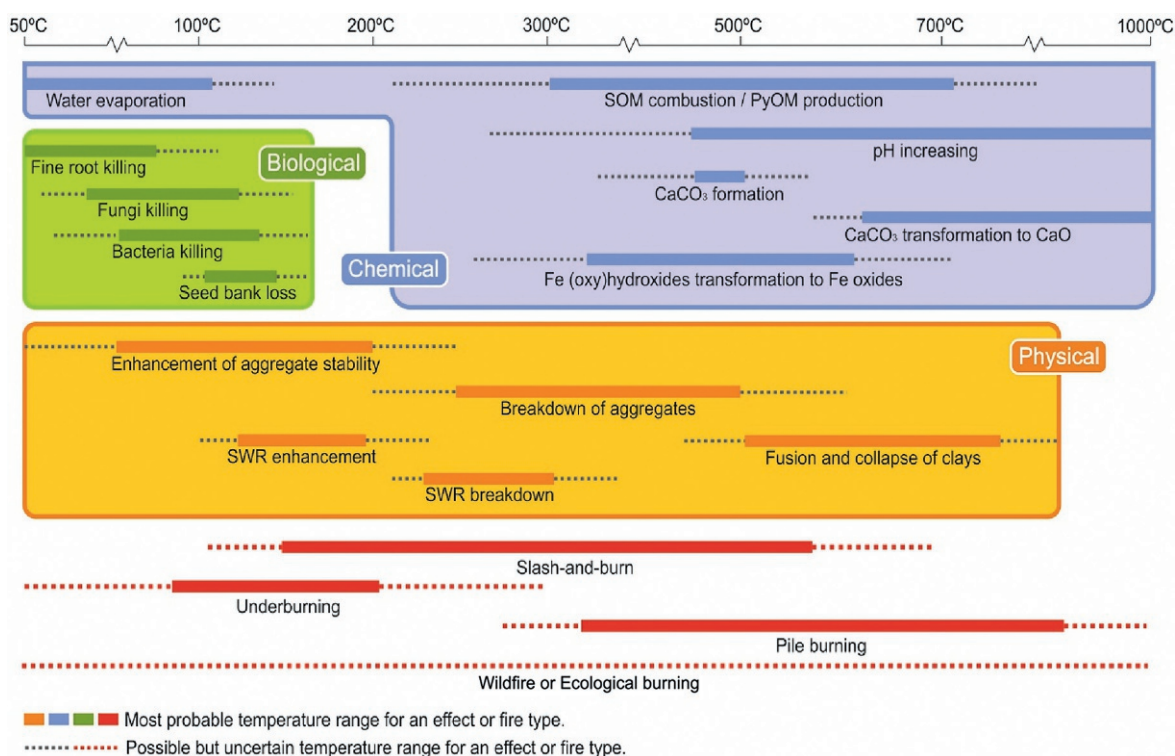

Fig. 1 Effects of fire on soil biological, chemical and physical characteristics and the temperature range at which these effects commonly occur. Red lines indicate the typical temperature ranges near the soil surface for different types of fires. Specific temperatures and associated soil effects will depend on the characteristics of each fire and soil. PyOM: Pyrogenic organic matter; SOM: Soil organic matter; SWR: Soil water repellency. Modified from Santín C and Doerr SH (2016) Fire effects on soils: The human dimension. *Proceedings of the Royal Society B: Biological Sciences* 371: 20150171.

Fig. 2 Soil before and after a moderate- to high intensity prescribed fire in a eucalypt forest (NSW, Australia). The litter and Oa layers (A) were burned by the fire and transformed into ash (B), whereas the Ah horizon experienced little direct impact. Maximum temperatures recorded using thermocouple sensors: litter: 577 °C; Oa: 400 °C; Ah: 59 °C. Photos S. Doerr; From Santín C, Otero XL, Doerr SH and Chafer CJ (2018) Impact of a moderate/high-severity prescribed eucalypt forest fire on soil phosphorous stocks and partitioning. *Science of the Total Environment* 621: 1103–1114.

Where the soil organic matter (SOM) content is sufficiently high (i.e., peats and other organic-rich soils), combustion of the soil itself may occur. This typically involves slow, smoldering combustion at temperatures in the region of ~600 °C that can consume soil layers to many decimeters depth and lead to extensive heating of any adjacent mineral soil (Fig. 3). Smoldering peat fires are very difficult to extinguish and in extreme cases can continue throughout a winter season even under snow cover (also known as overwintering or ‘zombie’ fires; Scholten et al., 2021).

Direct effects of fire

Soil chemical and mineralogical characteristics

Apart from the loss of water from evaporation, the key effects from heating and combustion concern SOM, nutrients, pH and, especially at higher temperatures, soil mineralogical transformations. Given that SOM is typically most abundant in the uppermost layers of soil where the heating during fire is also at its maximum, SOM is especially affected by fire.

Soil organic matter content and soil carbon stocks

Reported effects of fire on SOM stocks vary from negligible to substantial decreases or increases. This is a reflection of the wide range of fires studied. For mineral soils, low-severity fires have little impact on the SOM pool and associated carbon (C) stocks. In more severe fires where the soil can experience substantial heating (>200–300 °C), decreases in soil organic carbon (SOC) have been observed. For example, for a moderate-high severity fire in eucalyptus forest over sandy soils near Sydney, complete combustion of the Oa horizon (maximum temperature: ~400 °C), was observed, whereas the C concentration in the Ah horizon (maximum temperature: ~50 °C) was not altered (Fig. 2; Santín et al., 2018). A study examining SOC at 0–5-cm soil depth after different severities of soil burn in pine forest and shrublands in NW Spain showed that the lowest severities of soil burn did not translate into a significant decrease of SOC, but the highest resulted in SOC losses of up to 86% (Vega et al., 2013). Fire can also increase SOC stocks, however, due to inputs of organic constituents from ash² and charred organic matter, which can become incorporated into the soil (Fig. 3; Francos et al., 2018).

Fires in areas with organic types of soils, such as peatlands, often consume only the aboveground vegetation such as grasses, mosses or shrubs due to the high water content of the soil horizons. Following drought, and in some cases exacerbated by anthropogenic deforestation or drainage, however, organic soils can be very susceptible to combustion. For example, the recurring

²Here we refer to ash as the particulate post-fire residue consisting of mineral materials and charred organic components (Bodí et al., 2014).

Fig. 3 Umbric Leptosol developed over granite 1 year after fire (Galicia, NW Spain). Three distinct layers can be identified: (a) has suffered near-complete SOC combustion with loss of soil structure; (b) a substantial amount of SOC remains in the form of PyC materials formed by pyrolysis; (c) SOC-rich layer of largely unaffected by fire (photo C. Santín).

peatland fires in parts of Indonesia, which have affected large areas of degraded peatland soils over the last two decades, have led to substantial losses of peat, large emissions of carbon to the atmosphere (e.g., in 2015 more than the annual fossil fuel C emissions of Japan in 2013; Field et al., 2016) and regional air quality problems. The increasing extent, frequency and severity of boreal peatland fires observed in recent years associated with climate change are thought to have caused an overall decline in peatland C stocks with SOC losses from peat combustion exceeding the rate of peat accumulation in some regions in the globally important SOC store (Walker et al., 2019).

Soil organic matter composition

The combustion of SOM leads to mineralization and loss of organic components through volatilization and oxidation. When soil temperatures exceed 200–300 °C, the formation of new pyrogenic organic compounds in zones of incomplete combustion also begins to occur, in addition to any input of charred organic constituents from the partially combusted vegetation, litter and overlying organic layers (Santín and Doerr, 2016). Charring of SOM reduces oxygen-rich functional groups through dehydration and dehydrogenation reaction. In the lipid fraction, a reduction of the chain lengths is observed by thermal cracking. Cellulose undergoes aromatization and, at higher temperatures, polycyclic aromatic hydrocarbons begin to form (Knicker, 2007).

The term ‘pyrogenic carbon’ (PyC) is widely used to refer to the whole range of pyrogenic organic materials from partially charred vegetal biomass through to charcoal and soot (Santín et al., 2016). PyC is a broad continuum of C materials ranging from biolabile depolymerization products to highly degradation-resistant condensation products. Charring induces mainly aromatization and condensation reactions, which result in increased resistance against degradation of PyC. Whilst not inert (as assumed in the past) it has become clear that PyC exhibits a resistance to biochemical degradation in the environment that is orders of magnitude higher than its unburned precursors (Santín et al., 2016). It therefore plays an important role in the overall carbon budget of fires and the global carbon cycle. Its annual production is equivalent to ~12% annual C emissions from landscape fires (Jones et al., 2019), leading to a net C accumulation in some fire affected regions (Bowring et al., 2022). Soils are one of the largest pools of PyC in the Earth system; it accounts for ~14% of the global SOC stock (Reisser et al., 2016).

The formation of PyC is a medium- to long-term effect of fire on soil chemical properties, whereas, the overall effects of fire on SOM quantity and composition are many and highly site specific. There is therefore little that can be predicted in terms of universal effects and trends of fire on SOM, except that where the soil system is resilient to fire overall, a recovery towards a pre-disturbance equilibrium SOM quantity and quality can be expected.

Nutrients

The direct impact of heating and combustion processes in the soil is usually the volatilization of nutrients such as organic nitrogen (N) and phosphorus (P), which, in principle, leads to an overall loss. The loss of the different elements depends on their volatilization temperatures, with N and P being lost at lower temperatures ($\sim 500^\circ\text{C}$ and 700°C , respectively) than elements such as Ca (calcium), Mn (manganese) or Mg (magnesium) that need very high temperatures ($>1000^\circ\text{C}$) and, therefore, usually remain in the burned residues (Bodí et al., 2014). The overall direct effect of burning, however, is often an increase in nutrients such as phosphorus or calcium in surface soils (Pellegrini and Jackson, 2020). This is mostly due to leaching from, or the direct incorporation of, nutrient rich ash from vegetation deposited at the soil surface (Caon et al., 2014). During heating, conversion of organic to inorganic forms occurs; the latter being more accessible to plants and microorganisms. This fertilizing effect has long been taken advantage of in agriculture, such as slash and burn in shifting cultivation in tropical forest regions or stubble burning following harvesting in croplands (Maass, 1995). This fertilization effect, however, is rather transient and postfire erosion processes can lead to a substantial net loss of nutrients in the longer term (Caon et al., 2014; Santín et al., 2018).

pH

Following fire, an increase in soil pH is commonly observed, especially in acidic soils immediately after burning, with up to 3 units having been reported (Ulery and Graham, 1993). This is associated with the denaturation of organic acids and the release of bases from the combustion of organic matter (Certini, 2005). Much of the increase in pH near the soil surface can arise from the ash layer that is commonly deposited on the soil surface during fire. Vegetation fire ash is rich in alkaline cations (e.g., Ca^{2+} , Mg^{2+} , K^+ , potassium) and can exceed pH 9–11 in solution (Bodí et al., 2014). Its effect on soil, together with any increases in pH from in situ changes in the soil, are relatively short-lived when soils are exposed to prolonged or repeated periods of rainfall.

Soil mineralogical composition

Most fires have little impact on soil mineralogy except where sustained heating can make soil temperature exceeds $300\text{--}500^\circ\text{C}$, for example under smoldering logs or slash burns. Dehydroxylation, converting iron oxyhydroxides such as goethite, $[\text{FeO}(\text{OH})]$ to iron oxides such as hematite $[\text{Fe}_2\text{O}_3]$ (Fig. 1), is often evident by the red color of strongly heated soils (Certini, 2005). In the presence of organic matter or some other reducing agent, magnetic minerals such as magnetite and maghemite can also be formed in Fe-rich soil, which are used in archaeological studies for evidence of fire (Oldfield, 1999). Carbonates such as calcium carbonate (CaCO_3 —a key mineral in calcareous soils), dissociate to oxides between 580°C and 1100°C depending on the carbonate compound in question. Perhaps more important, however, is the addition of CaCO_3 to the soil from ash produced in severe fires (Bodí et al., 2014).

Soil physical characteristics

Water repellency and other hydrological characteristics

A common observation following fire is the presence of soil water repellency (SWR; also termed water repellence; hydrophobicity; Fig. 4). It is caused by hydrophobic compounds such as aliphatic or amphiphilic organic molecules covering soil particle surfaces or accumulating in soil pore spaces. These compounds can be produced in situ in the soil by, for example, fungal or microbial activity

Fig. 4 Strong water repellency following a severe wildfire in a eucalyptus forest near Sydney 2020, as indicating by a water droplet resting on sandy soil (photo S. Doerr).

or added from plant litter (Doerr et al., 2000) or hydrophobic ash (Bodí et al., 2014). The non-polar areas of these molecules have a low affinity to water, leading to an overall reduction in surface tension of the soil to below that of water ($72.75 \times 10^{-3} \text{ N m}^{-1}$ at 20°C). This means that water is more attracted to itself than to the surface it is in contact with, resulting in no spreading and infiltration of water (Fig. 4). Depending on the severity and persistence of SWR, this can cause a delay in infiltration or non-wetting of the most water repellent area of a soil. Many soils exhibit natural levels of water repellency at low soil moisture contents, however, fire can modify and often enhance its presence by (i) removing the litter layer and making it more apparent, (ii) drying the soil, (iii) adding hydrophobic compounds to the soil released during the burning of organic matter, and (iv) in situ enhancement of SWR by heating and modifying organic matter in the soil (Doerr et al., 2000). The temperatures and associated parameters at which changes in SWR occur have been the subject of numerous studies. Common observations are that SWR begins to be enhanced below 100°C , can be strongly enhanced up to $\sim 250\text{--}270^\circ\text{C}$, but is generally destroyed at higher temperatures. Oxidation of the causal compounds seems to be key in the elimination of SWR as the threshold destruction temperature can be increased to $>500^\circ\text{C}$ in the absence of oxygen. In fires that result in a high severity of soil burn, heating can be sufficient to eliminate SWR in the top few millimeters or centimeters of soil, which are then underlain by a layer of enhanced water repellency (Shakesby and Doerr, 2006).

Soil water repellency can not only lead to reduced or impeded infiltration, but its often highly variable spatial nature also leads to the formation of preferential flow pathways and enhanced spatial variation in soil moisture. The net effect at the landscape scale is lower soil water holding capacity, and enhanced overland flow, preferential flow and associated stream runoff (Fig. 5; Doerr et al., 2000).

The loss of organic matter, a breakdown of aggregates or the clogging of pores from ash ingress or the formation of an ash crust (Bodí et al., 2014) can also lead to a reduction in soil infiltration capacity and enhanced overland flow irrespective of any SWR. However, the permeability and water holding capacity of ash is generally greater than that of the underlying soil and, thus, the ash layer typically reduces overland flow (Bodí et al., 2014).

Aggregate stability and bulk density

Moderate soil heating can enhance aggregate stability associated with an increase in particle surface water repellency. At higher temperatures, effects can vary from disaggregation to strong aggregation at high temperatures if recrystallization of minerals (e.g., Fe and Al (aluminium) oxyhydroxides) occurs (Fig. 1; Mataix-Solera et al., 2011). Bulk density can increase following fire where aggregate collapse and the ingress of fine ash leads to a reduction of pore space (Certini, 2005).

Soil biological characteristics

Microorganisms

The direct, short-term effects are often a decrease and modification of the soil microbial community through heat induced mortality. This begins to occur above 60–80 °C, a temperature that can easily be reached in the top few centimeters of soil especially when the soil is moist, which facilitates heat transmission for temperatures to reach 100 °C. In general, fungi, especially ectomycorrhizal types, appear to be more heat sensitive than bacteria (Pellegrini and Jackson, 2020). In ecosystems where fires are rare they may cause major shifts in, for example, fungal community that last years or even decades. In ecosystems adapted to frequent fires, fire may also be necessary to maintain fungal communities (Fox et al., 2022). In extreme cases, soil heating can lead to sterilization of the topsoil layer, however, unless heat penetration is very deep and extensive (e.g., under large pile burns), rapid recolonization from subsurface layers or adjacent areas that experienced less soil heating will normally occur (Certini et al., 2021). Immediately after fire, alterations in soil pH, nutrients and SOM (including the formation of toxic compounds) can affect the activity and composition of soil microbiota. For example, an increase in heterotrophic bacteria activity associated with an increase in soluble carbon and nutrients is commonly observed in the post-fire period. This initial increase is generally followed by a decrease once the easily accessible carbon and nitrogen forms have been depleted. An increased ratio of bacteria to fungi is thought to be associated with the increase in pH from ash. Although an overall reduction in soil microbial activity in the top few centimeters is commonly found in the first few years after fire, modification of the microbial and fungal soil biome with recolonization from adjacent soil areas and aerial deposition of microbes and spores may be the more important medium-term fire impact (Certini et al., 2021). The proliferation of edible pyrophilic fungi such as those of the *Morchella* genus after fire can be of substantial local economic importance (Larson et al., 2016).

Invertebrates

Apart from some flying insects, most soil dwelling invertebrates easily succumb to fire due to their relative immobility and sensitivity to heat. For example, the lethal temperature for many soil arthropods can be as low as 40 °C resulting in very high mortality for those present in the litter and topsoil layers. Mortality is reduced for earthworms and other burrowing animals when they escape the flames or the heat shock by migrating to deeper layers. However, rather than direct mortality, the indirect effects of fire on food resources may have a greater impact overall, causing the invertebrate population to decline. This can especially affect herbivore species such as litter-dwelling detritivores following extensive high-severity fires. On the other hand, other types of organism may even increase in abundance after the fire due to, for example, stimulation of emergence of adults from increases in soil temperature or greater availability of dead wood (Molinas-González et al., 2019).

Where invertebrate mortality has been high, recovery proceeds gradually, firstly by highly mobile species, from nearby unburned areas or patches of low fire severity. Thus, for example, recolonization of carabids occurs sooner than that of soil dwelling macrofauna, while arachnids, earthworms, molluscs and myriapods are rather slow colonizers (Certini et al., 2021). Complete recovery of the invertebrate community after fire may take years, or even decades, depending on fire severity, its patchiness and shape and extent of the burned area. It is important to consider, however, that fire also creates new habitats and, beyond the immediate area burned, also increases habitat diversity over larger spatial and temporal dimensions. Burned areas can attract pioneer species that take advantage of dead vegetation or new herbaceous growth, and some invertebrates, such as ants or termites have dwellings that can be resistant to fire. Ultimately most invertebrates (and other animal species) recover best from a single fire with patchy severity, followed by a sufficiently long recovery period within the normal interval for fire return of a given ecosystem (Certini et al., 2021).

Soil seed bank

The soil seed bank is an important source of resilience in ecosystems to perturbations. The direct effect of fire on the seedbank is closely related with the temperature reached in the soil. Thus, fire behavior, such as its intensity and residence time together with soil thermal properties, determine the amount of soil heating. The associated effects on the seedbank tend to be spatially variable within a burned area. The ability of seeds to respond to fire also differs between plant species and with the distribution of seeds in the soil profile (Kwiatkowska-Falinska et al., 2014) given that soil temperatures decrease markedly with depth during burning (Bradstock and Auld, 1995). In some fire-adapted species, seed germination is also influenced by the indirect effects of fire like smoke or charred wood (Read et al., 2000). Thus, if temperatures in the soil profile remain below that at which damage to seeds occurs, fire can promote their germination through heating, smoke stimulus, the change in soil nutrient levels, and by providing greater access to water and light due to temporary removal of plant cover (Snyman, 2005). Much research has been conducted on the effects of fires on soil seed banks in fire-adapted ecosystems, especially in Mediterranean regions. Other ecosystems where fires have been rare, have seen limited attention. This is an important research gap given that fire is becoming more prevalent in some of these.

Indirect effects of fire

Some of the most severe and lasting effects of fire on soil can be indirect and often occur gradually over the post-fire period; an important consideration when evaluating any effects on the soil of a given fire (Santín and Doerr, 2016). Major impacts can arise from the loss of vegetation and litter cover, and, where relevant, the immediate or delayed mortality of plants and roots. This has

implications for soil biogeochemical processes, soil thermal regime and runoff and erosion. The reduction or complete loss of soil cover, combined in some cases with reduction in soil stability and enhanced water repellency, allow erosive rainfall to affect the soil surface directly, leading to splash erosion, enhanced particle entrainment, and accelerated overland flow and erosion (Fig. 5). These processes can also trigger large-scale gully erosion and mass movement events. Especially in steep terrain, substantial soil- and associated carbon and nutrient losses can occur. Published values of soil losses range between 0.1 and 41 Mg ha⁻¹ per year after moderate to severe fires compared to 0.003–0.1 Mg ha⁻¹ in comparable long unburned terrain (Shakesby and Doerr, 2006). The ‘window of disturbance’ during which the hydrogeomorphological response remains enhanced will vary with fire severity, terrain and rates of vegetation recovery and can last from a few weeks to many years. Given that surface soil holds the greatest amount of soil organic matter, nutrients and microorganisms, fire-triggered erosion of surface soil is often viewed as ‘soil destruction’, but it is important to remember that wildfires and soil erosion are often natural processes. While on-site losses may be detrimental, the redistribution of organic- and nutrient-rich sediment often promotes the formation of fertile soils in depositional areas, in riparian zones and floodplains, both within and well beyond a given burned area. Only material that is deposited in lacustrine or marine sediments can therefore be considered as being removed from the pedosphere in the longer term (Santín and Doerr, 2016).

Of relevance are also the inputs of new material to the soil triggered by fire in addition to sediment redistribution discussed above. For example, some of the immediate effects of the deposition of wildfire ash have already been highlighted under the direct effects of fire. While some ash is derived directly from charred topsoil, much of it typically originates from the burned aboveground biomass with production values up to 150 Mg ha⁻¹ having been reported. Some of the ash will be redistributed by wind or water erosion, but some will become incorporated into the soil via infiltrating water or bioturbation, adding nutrients and carbon gradually to the soil. Further gradual inputs of organic materials also occur in the form of decaying unburned vegetation killed by the fire, and the gradual incorporation of PyC deposited on the soil surface. The potential for PyC (or its human-made ‘cousin’: biochar) to increase the fertility of soils has been the focus of much research since the discovery of the fertile Terra preta soils in Amazonia (Santín and Doerr, 2016) and it is the basis of biochar technology (Jeffery et al., 2011).

A further process leading to the addition to soil is fire-induced breakdown of parent material (i.e., rock and regolith) into smaller fragments. The high temperature gradient in exposed rock surfaces caused by fire leads to spalling, the flaking of typically mm–cm thick small rock fragments (Fig. 6). This weathering process has, for example, been estimated to be similar or orders of magnitude more effective over repeated fire cycles than other weathering processes generating sediment (Buckman et al., 2021). In addition, especially where fires cause high tree mortality (stand replacing fires), the accelerated uprooting of trees brings regolith or deep soil to the surface and exposes it to accelerated weathering. Thus, while the accelerated losses of soil and associated fertility in the post-fire period are often of concern in addition to the direct impact of fire, the inputs of new material triggered by fire also need to be considered.

Fig. 6 Fire-induced spalling on rock surface, and rock fragments derived from it on the ground, after the unprecedented 2019–2020 Australian bushfire season (photo S. Doerr).

Finally, during the post-fire vegetation recovery process, changes in vegetation composition, for example, from pioneer to climax species composition, are accompanied by changes in micro-climate, hydrology and biogeochemical processes, which in turn affect soil processes. Where alterations in fire regimes or human-driven deforestation and degradation fires occur, these can result in long-term or even permanent change in the vegetation cover, which will also have implications for soil processes.

Conclusions

Fire is a common perturbation in many vegetated regions and can have profound effects on soil physical, chemical and biological process. These arise from direct impacts through heating and combustion during the fire and indirect processes in the postfire period such as loss of vegetation cover and accelerated erosion. The effect of these processes may diverge. For example, the addition of nutrients from ash in the short-term may be more than offset on steep slopes by nutrient losses from accelerated erosion in the post-fire period. In most cases, wildfires or management burns of low severity will have little lasting impact on soil, whereas severe fires, especially when they occur more frequently than is the norm for a given ecosystem, can lead to very detrimental and long-lasting effects on the soil. The soil degradational impacts of fire are therefore often a focus after severe fires, however, it is important to consider that fire has been a recurring land surface process for over 420 million years affecting pedogenesis. On balance, and excluding areas where the occurrence of extremely severe or frequent fires prevent medium-term recovery or de novo formation of soil, fire has probably been an important factor of soil formation in many fire-affected regions around of the globe.

Abstract

Microbial–mineral interfacial reactions are crucial in the development and functioning of soil. We present basic mechanisms by which microorganisms and the polymers they secrete attach to mineral surfaces, followed by discussion on three fundamental consequences of these reactions: weathering (including secondary mineral formation), element cycling (including organic matter turnover and accumulation), and formation of physical structure in soil. We also point out potentially important questions arising from the microbe–organic matter–mineral interactions.

Key points

- Microbe–mineral interfacial reactions result from an interplay of microbial cells and mineral surface through a range of bonding mechanisms.
- Microbial interface reactions drive important soil processes (e.g., weathering, elemental cycling, and soil structure formation), provide nutrients and more extensive and heterogeneous habitats to support microbial and plant life.
- Therefore, microbial interface reactions are essential components of pedogenesis and soil functioning.

Introduction

Microorganisms (microbes) and the organic matter (OM) they process, synthesize, and reside in, are often in contact with, or in the vicinity of, mineral and rock surfaces in soils. Microbe–OM–mineral interactions are ubiquitous on the Earth's surface, including marine sediments and even aerosols, and their history is presumably as old as the origin of life. As microbes are typical first colonizers in most terrestrial settings, soil genesis is largely induced and driven by microbe–OM–mineral interactions. As a result, many soil processes and functions, such as nutrient cycling, water holding and filtration, structural formation, and carbon (C) storage, are directly or indirectly linked to the reactions taking place at microbe–OM–mineral interfaces (Fig. 1). In this chapter, we focus primarily on direct mineral–microbe interactions, since other aspects of the mineral–OM–microbe continuum (e.g., OM decomposition, organic–mineral interactions, rhizosphere processes) are covered in other chapters.

First, we summarize and explain the fundamental factors of microbe–mineral interfacial reactions, starting from microbial cell surface characteristics to the bonding mechanisms. We then discuss the consequences of mineral–OM–microbial interfacial reactions by focusing on microbially-mediated weathering, elemental cycling, and soil aggregate formation.

Fig. 1 Examples of mineral–organic matter–microbe interactions that primarily take place at the solid–aqueous interface. Solid phases in soil systems can be minerals, insoluble biomolecules (plant and microbial detritus and metabolites), and living and dead organisms.

Microbe attachment at mineral interfaces

Microbes can directly attach or adhere to mineral surfaces or indirectly via the extracellular compounds they secrete (Wingender et al., 1999). A range of binding mechanisms facilitates the attachment of microbes to mineral surfaces. We use the term ‘adhesion’ when multiple bonding forces render cell attachment hardly reversible. We provide basic information on microbial cell surface structure, including extracellular polymers that often surround cells, and the surface charge characteristics of those materials. Then we discuss the different types of forces involved in cell–mineral attachment. With charges arising from the functional groups on cell surfaces, coulombic interactions control the attachment of cells to charged mineral surfaces. Non-coulombic interactions may additionally come into play, especially on uncharged surfaces. Finally, we discuss the consequences of multiple forces being involved simultaneously or in sequence during surface interactions of cells and minerals.

Microbial cell surface structure and chemistry

Cell surface structure

Cell surface structure varies strongly among bacteria (Gram-positive vs. Gram-negative bacteria) and between bacteria and fungi, although all these organisms having plasma membranes (composed of lipid bilayers) underneath their cell walls. The cell wall of Gram-positive bacteria (Fig. 2) is characterized by a thick layer (15–80 nm) of peptidoglycan, a porous cross-linked polymer consisting of a glycan backbone (a repeat polymer of two amino sugars) and peptide cross-linkages, giving it a semi-rigid structure. Fibers embedded in the peptidoglycan layer and sometimes extending away from the cell surface are composed of teichoic acids, glycopolymers having phosphodiester-linked polyol repeat units. Their main function is to provide flexibility and attract cations due to their strong negative charges. In contrast, the cell wall of Gram-negative bacteria consists of an outer membrane (made up of lipids, proteins, lipopolysaccharides) above a thin layer (1–2 nm) of peptidoglycan (Fig. 2). Lipopolysaccharides, composed of lipid-A (phosphorylated glucosamine disaccharide) and polysaccharide are a major source of negative charge in Gram-negative bacterial cell walls and can extend their branches away from the cell surface for tens of nanometers. In addition to cell walls, some bacteria also have appendages that enable active surface attachment, including flagella, fimbriae, and pili. While flagella are primarily for swimming and attachment, fimbriae and pili play crucial roles in surface attachment. These thin hairlike external protein appendages are 1 to 20 μm in length and often occur in large numbers. At the end of each fimbria are special proteins, so-called adhesins. These surface structures have the potential to mediate bacterial attachment directly to solids.

The fungal cell wall is mainly composed of polysaccharides, proteins, and lipids, and occasionally contains melanin, polyphosphate, or inorganic acids (Fig. 3). The major polysaccharides are glucans (β -1,3- (30–80%), β -1,6-, and α -1,3-), chitin (1–15%),

Fig. 2 Structure of bacterial cell wall. Plasma membrane, peptidoglycan, and proteins present in both Gram-positive and Gram-negative bacteria. Lipoprotein covalently binds with peptidoglycan on one side, and embeds the other polar side into the outer membrane, strengthening the integrity. Fibrillar surface protein (e.g. fibrillar adhesins) and capsular polysaccharide may also be present on the cell wall, controlling the cell attachment to solid surfaces. Modified from Chorover J (2022) 5. Microbe–biomolecule–Mineral interfacial reactions. In: Yang Y, Keiluweit M, Senesi N, and Xing B (eds.) *Multi-Scale Biogeochemical Processes in Soil Ecosystems: Critical Reactions and Resilience to Climate Changes*. pp. 117–140. John Wiley & Sons, Inc.

Fig. 3 Structure of fungal cell wall. Polysaccharides (i.e., glucans, chitin, mannan, galactomannan) are the major components of fungal cell walls. The structure is strengthened by protein and or other components such as pigments, lipids, or polysaccharides. Proteins contain O-linked galactomannans or mannans, or N-linked oligosaccharides. These proteins can covalently link to the cell wall either without or with a glycosylphosphatidylinositol (GPI) anchor. Over half of the cell wall proteins are GPI-anchored proteins. Modified from Free SJ (2013) Chapter Two - Fungal cell wall organization and biosynthesis. In: Friedmann T, Dunlap JC, and Goodwin SF (eds.) *Advances in Genetics*. pp. 33–82. Academic Press.

chitosan, mannans, and galactomannans (Free, 2013). Proteins are relatively more abundant in the outer part of the fungal cell wall, while carbohydrates occur primarily in the inner part (Fig. 3). The hyphal cell wall contains S-glucan, hydrophobins, and melanins (Feofilova, 2010). Structurally, glucans, chitin, and glycoproteins form three-dimensional linkages within the cell wall. Some of the glycoproteins are anchored to the cell membrane through glycosylphosphatidylinositol, GPI (Fig. 3). Hydrophobins are small, cysteine-rich proteins, secreted only from the aerial hyphae of filamentous fungi. Because of their amphiphilic property (Bromley et al., 2015), hydrophobins mediate attachment to hydrophobic surfaces (Feofilova, 2010). The composition of the functional groups on cell walls, including proteins (or amino acids) and some polysaccharides (mannans and galactomannans), determines the attachment to minerals.

Extracellular compounds and extracellular polymeric substances (EPS)

Microbes secrete various compounds, including organic acids and polymers such as extracellular enzymes. Perhaps most important for cell–mineral interface interactions are extracellular polymeric substances (EPS), which often cover microbial cell surfaces. The EPS mainly consist of polysaccharides and proteins, with minor amounts of enzymes, lipids, and nucleic acids (Flemming and Wingender, 2010).

The EPS promote cell-to-cell attachment and adhesion to mineral surfaces. In addition, EPS can protect microbes from predators and abiotic stress (i.e., extreme pH, drought, toxic chemicals, oxidative damage), and mediate enzyme activity, nutrient availability, and electron transport (Op De Beeck et al., 2021; Kaur et al., 2022). The role of EPS in soil processes, especially soil aggregation, has been studied extensively (see Section “Contribution to soil aggregate formation”). The EPS in the environment are grouped into three chemically and functionally different forms: capsular EPS on the surface of bacteria, biofilm EPS as the matrix of biofilms, and free EPS in the aqueous phase (Wingender et al., 1999).

Production of EPS is widespread across wide taxonomic groups of bacteria and fungi. The large investment of energy, C, and nutrients (in particular nitrogen (N)) for its synthesis suggests an evolutionary advantage of EPS production (Chenu and Cosentino, 2011). There are several reviews on the functions of EPS synthesized by bacteria (Tourney and Ngwenya, 2014) and fungi (Op De Beeck et al., 2021). The production and chemical composition of EPS varies with the microbial type (functions) and growth stage, together with environmental conditions (i.e., pH, temperature, water, and oxygen availability) (Kaur et al., 2022). The EPS could also provide a gradient of pH or ionic strength, controlling the diffusion of compounds both into and out of cells. With similar molecular composition, fungal EPS is expected to have similar physicochemical properties and, therefore, play similar roles as bacterial EPS for microbial life (Op De Beeck et al., 2021).

Functional group chemistry of cell surfaces

The surfaces of microorganisms feature carboxyl, phosphoryl, sulfuryl, amine, and hydroxyl groups that derive mainly from polysaccharides, proteins, lipids, and pigments in the cell wall (Chorover, 2022). These functional groups can either dissociate or become protonated in response to the changes in local pH conditions. Dissociation constants (pKa) of the functional groups on Gram-positive and Gram-negative bacteria, measured by potentiometric titration, are similar: 2–6 (carboxyl), 0.2–2.91 and 5.65–7.20 (pKa₁ and pKa₂ of phosphoryl), 9.6–10.8 (phenolic hydroxyl), and 9.1–10.6 (amine) (Hong and Brown, 2006). Fewer data are available for the functional groups on the fungal cell wall, but pKa ranges are likely to be comparable. Three types of dissociated protons were identified for *Rhizopus arrhizus* by Naja et al. (1999). At pH <4.5, released protons derived from phosphoryl or carboxyl groups. Between pH 4.5 and 7, carboxyl groups played a major part in proton dissociation. At pH >8, phenolic and amine groups contributed to the acidity. The EPS have similar functional groups as cell walls, with carboxyl, phosphate, amine, and hydroxyl groups dominating, and smaller contributions of sulfate, amide, and phosphodiester groups (Tourney and Ngwenya, 2014) (and the references therein). Therefore, the acidity of EPS is similar to that of bacterial and fungal cells, and generally ranges between 3 and 11 (Tourney and Ngwenya, 2014).

Carboxyl or phosphoryl groups dissociate and become negatively charged under acidic to neutral conditions. Amine and hydroxyl groups dissociate only under alkaline conditions, and thus, are positively- and non-charged, respectively, at neutral and acidic pH. Despite the wide variation in pKa values, soil microbial cells usually have a net negative charge within the common soil pH range (<8) because of the much larger abundances of carboxyl and phosphate groups than amine groups (Chorover, 2022).

Functional groups with varying pKa are heterogeneously distributed on cell walls and within EPS. Thus, despite the overall net negative charge of cells, positively and negatively charged groups may co-occur, allowing for electrostatic interactions with both negatively and positively charged ions and surfaces. The heterogeneity of surface charge can decrease electrostatic repulsion at the local scale and support irreversible particle attachment.

Cell-to-mineral attachment mechanisms

Coulombic interaction between cell and mineral

The charges arising from the functional groups on cell surfaces can attract solutes and facilitate attachment to solids with opposing charges. The two major types of coulombic interaction between cells and minerals are reversible electrostatic attraction and less reversible surface complexation.

Electrostatic interaction between microbe and mineral is controlled by the charges of cells and minerals, moderated by the solution pH. As mentioned, the net surface charge of microorganisms is usually negative within the common soil pH range (<8) due to the dominance of acidic groups (see Section “Functional group chemistry of cell surfaces”). The surface charge of minerals is dictated by their point of zero charges (PZC). The average PZC of common minerals in soil is 8.9 for boehmite, 9.9 for gibbsite, 7.6–9.1 for hematite, 8.1–8.6 for goethite, 7.1 for lepidocrocite, 7.9–8.1 for ferrihydrite, 4.9 for manganese dioxide (MnO₂), and 3.0 for quartz (Kosmulski, 2009). Consequently, within the common soil pH range (<8), iron (Fe) and aluminum (Al) hydrous oxides are mainly positively charged, while manganese (Mn) oxides and silicates are negatively charged. Therefore, microbes are likely to bind electrostatically to Fe or Al hydrous oxides via their negatively-charged functional surface groups (carboxyl, phosphoryl, sulfuryl, phenol), and to Mn oxides and silicates via amino groups.

Cation bridging is another type of coulombic interaction. Multivalent cations (e.g., Ca²⁺, Mg²⁺, Fe³⁺, Al³⁺, Si⁴⁺) can act as bridges between negatively charged minerals and negatively charged cell surfaces or EPS, thus overcoming the electrostatic repulsion between the two constituents. Both direct electrostatic interactions and cation bridging are reversible and sensitive to the changes in solution chemistry, such as pH and ionic strength.

Surface complexation can occur between specific functional groups and certain mineral surface sites. As both electrostatic attraction and covalent bonds are involved, the reaction results in much stronger, and thus, less reversible attachment. For instance, initial bacterial attachment to Fe oxides involves inner-sphere complexation of bacterial phosphate groups at the surfaces of Fe oxides (Parikh and Chorover, 2006). Bacterial EPS, containing both polysaccharide-rich and protein-rich components, often exhibit

strong metal complexation capabilities, which also makes them prone to forming strong surface complexes on Al and Fe hydrous oxides (Chorover, 2022). In addition, EPS can co-precipitate with metals when their solution concentrations are high enough, which may also promote cell–mineral interactions.

Non-coulombic interaction between cell and mineral

Uncharged organic surfaces can associate with uncharged mineral surfaces by non-coulombic interactions (e.g., dipole interactions, i.e., due to van der Waals and London forces, or hydrogen (H) bonds). The EPS contain large uncharged components, such as non-ionic polysaccharides and proteins. Uncharged portions are also present on microbial surfaces, including, teichoic acids, and lipopolysaccharides (see Section “Cell surface structure”). These interactions may be mediated via water molecules, which are dipoles, forming so-called water bridges. Thus, non-coulombic interaction can play a role in cell and or EPS attachment to mineral surfaces. Short-distance forces may come into play when cells bind through other mechanisms, they then add to the strength of adhesion.

Hydrophobic interaction can take place at cell/EPS–mineral interfaces. While the majority of metal oxides and clay minerals are hydrophilic, hydrophobicity differs among minerals. The relative hydrophobicity of some common soil minerals is, in decreasing order, birnessite, montmorillonite, kaolinite, quartz, goethite, and mica (Hong et al., 2012). Hematite is moderately hydrophobic, while goethite and aluminum hydroxide are hydrophilic. Other factors, such as particle size and crystallinity and environmental conditions, can also affect the hydrophobicity of minerals. On the other hand, the hydrophobicity of microbial cells depends on the relative abundance of hydrophobic and hydrophilic surface structures. Lipids and proteins on microbial cell walls tend to be relatively hydrophobic; polysaccharides are hydrophilic. For EPS, hydrated polysaccharides contribute to hydrophilicity, and DNA, proteins, and lipopolysaccharides tend to be relatively hydrophobic (More et al., 2014). The methyl- and acetyl-functional groups on polysaccharides are also attributed to the hydrophobicity of EPS (Flemming and Wingender, 2010). Cells or excreted polymers can bind on particles, and in that, can change their surface charge or hydrophobicity. The binding of intact bacterial cells or cell fragments enhances the hydrophobicity of minerals such as hematite (Poorni and Natarajan, 2013). The EPS tend to decrease the hydrophobicity of mineral surfaces, whereas extracellular proteins increase the hydrophobicity (Poorni and Natarajan, 2013). Environmental conditions, such as ionic strength and pH, affect the electrostatic repulsion, functional group protonation, and hydrophobicity of cells, EPS, and minerals (Li et al., 2019; Tournay and Ngwenya, 2014; Guhra et al., 2022). For example, the carboxyl groups of fatty acids on the outer cell wall of *Thiobacillus ferrooxidans* (*T. ferrooxidans*) protonate under acidic conditions, which enhances hydrophobicity and cell adhesion to mineral surfaces (Solari et al., 1992).

Filamentous fungi synthesize and secrete hydrophobins (see Section “Cell surface structure”) that confer hydrophobicity to fungal surfaces in contact with air, and thus, mediate attachment of hyphae to hydrophobic surfaces. Some bacterial colonies embedded in EPS (i.e., biofilms) also exhibit hydrophobicity caused by surface-active proteins having amphiphilic structures (bacterial hydrophobins) (Bromley et al., 2015).

Interplay of multiple binding mechanisms at the cell–mineral interface

Microbe–mineral interactions usually involve multiple forces, including both long-range forces (mostly electrostatic interactions) and short-range ones (van der Waals forces, hydrophobic effects, chemical bonding). The relative importance of different forces changes with the environmental conditions. Given its complexity, we focus on two topics and discuss multiple binding mechanisms that take place either in sequence or simultaneously.

Forces involved in a single bacterium on a mineral surface

We start with a simple scenario where a typical bacterium approaches and attaches to a negatively-charged mineral surface (Fig. 4, adapted from Liao et al. (2015)). A bacterium equipped with flagella can enhance the attachment by moving toward the surface and overcoming the surface water barrier. While only a weak van der Waals force may be present at >50 nm distance, the bacterium closer to the surface may face a hydrodynamic boundary layer and repulsive electrostatic forces. When the distance becomes approximately 2–10 nm, both repulsive and attractive electrostatic interactions may occur depending on the range of functional groups distributed non-uniformly on the cell surface (section 2.1.3). Hydrophobic groups on the cell surface (e.g., fimbriae and ‘hairy’ polymers, see Section “Cell surface structure”) may expel water molecules adsorbed on the surface at this distance. The exclusion of surface water molecules during the hydrophobic interaction between cells and surfaces would increase the entropy and lower the Gibbs free energy (Rosenberg, 1991). At <1 nm distances, a variety of chemical interactions (ligand exchange, ion bridging, van der Waals) between the cell and the surface enable and reinforce the attachment (i.e., adhesion).

Upon drying, cells can approach the mineral surface due to evaporative loss of water films? Thus, under dry conditions or in soil undergoing wet–dry cycles, non-coulombic forces may become increasingly important. Water stress (as well as predation pressure) could induce increased EPS production by bacteria (Kaur et al., 2022) and, therefore, promote EPS-induced complex interactions (next section).

Limited detachment of adhering cells (i.e., reduced reversibility of cell–mineral attachment) has been observed frequently. Spectroscopic studies examining cell–mineral interfaces revealed time-dependent changes in bonds formed at mineral surfaces. On Fe oxide (hematite), the bacterial attachment started by inner-sphere complexation with phosphate groups (formation of surface phosphorus (P)–oxygen (O)–Fe bonds), followed by bonding of carboxylates (Chorover, 2022). The importance of non-coulombic interactions at the cell–mineral interface increases in the presence of EPS (see next section).

Fig. 4 Forces involved as a cell approaches a net negatively charged mineral surface. Modified from Liao C, Liang X, Soupir ML, and Jarboe LR (2015) Cellular, particle and environmental parameters influencing attachment in surface waters: A review. *Journal of Applied Microbiology* 119: 315–330.

Role of EPS at the cell-mineral interface

The EPS contain multiple functional groups (see Section “Functional group chemistry of cell surfaces”) as well as uncharged components and moieties, allowing their interaction with mineral surfaces through electrostatic interaction (at distance) and by van der Waals interactions, H bonds, cation bridges, cation–anion exchange, or hydrophobic interactions at proximity (Chorover, 2022). The co-occurrence of coulombic and non-coulombic interactions makes them act as effective glues, promoting adhesion among cells and of cells to minerals.

Bacteria in natural environments can be present in the form of biofilm (clusters of microbial communities embedded in EPS), although the relative abundance of biofilm-forming bacteria in the soil system is largely unknown. The formation of biofilms starts with reversible surface attachment, followed by irreversible attachment, colonization, biofilm maturation, and eventually dispersion (Sauer, 2003). The transformation from reversible to irreversible attachment is facilitated by EPS excretion.

The EPS contain both hydrophobic (DNA, proteins, lipopolysaccharides) and hydrophilic (polysaccharides) components (More et al., 2014). Due to the variation in EPS composition as well as mineral surface chemistry, EPS can have both positive and negative effects on cell adhesion (Tourney and Ngwenya, 2014). Binding of EPS has also been reported to decrease the hydrophobicity of minerals (Poorni and Natarajan, 2013). Coverage of minerals by negatively charged EPS can decrease the surface’s isoelectric point and either promote aggregation or, depending on the extent of coverage, generate electrostatic repulsion among colloidal mineral particles (Guhra et al., 2022, reference therein). In addition, changes in pH can alter the protonation or deprotonation of functional groups and/or induce EPS structural changes, which in turn affects EPS–cell–mineral interactions.

Consequences of microbial–mineral interfacial reactions

Microbe–mineral interactions have significant impacts on soil processes, such as biogeochemical cycling, at the pedon, ecosystem, catchment, and even global scale. The initial and one of the most profound consequences of the interactions is rock weathering, which includes the physical breakdown and chemical dissolution of rock minerals as well as the neoformation of secondary minerals that are often more chemically reactive than primary minerals. Driven by their needs for nutrients and energy, microbial activities in soil strongly control the cycling of elements that are important for biota. Microbial–mineral interaction also contributes to soil aggregation and the development of porous soil structure, which supports water storage and gas diffusion, ensuring terrestrial ecosystem functioning.

Microbially-mediated weathering and formation of minerals

Rock weathering starts with the water percolating into pores and cracks, largely created by abiotic effects, such as fluctuation in temperature and moisture (e.g., freeze–thaw and wet–dry cycles). By colonizing and dissolving the surface of minerals, microbes acquire nutrients or energy, sequester toxic substrates, or create environments suited for their life (Chorover, 2022). Initial colonizers include (a) chemolithoautotrophs that obtain energy from the oxidation of reduced elements in minerals (e.g., Fe, Mn, sulfur (S)) while fixing CO₂, (b) photoautotrophic bacteria, cyanobacteria, and algae (particularly in nutrient-poor systems exposed to sunlight), and (c) heterotrophic microbes that acquire energy by oxidizing organic C fixed by autotrophs (Chorover, 2022). Their successive colonization and proliferation result in partial or full destruction of minerals by both physical and chemical effects as well as the formation of secondary, often highly reactive, minerals. These neoformed mineral phases, in turn, enhance the accumulation of microbial products (extracellular polymers, necromass) by sorption, complexation, and aggregation reactions.

Microbially-mediated mineral or rock weathering and transformation have been studied for fungi (Smits and Wallander, 2017; Martino and Perotto, 2010) and bacteria (Uroz et al., 2009). Here, we briefly summarize the physical and chemical mineral weathering due to microbe–mineral interfacial interactions.

Physical aspects

Fungi and lichens are among the first colonizers. Compared to bacteria, fungi have the advantage of actively extending hyphae even to the hydrophobic and dry surfaces of minerals (sections “Cell surface structure” and “Non-coulombic interaction between cell and mineral”). Fungi can sense the size and type of minerals to maximize the benefit of foraging, and physically destruct minerals by widening existing pores and cracks as their hyphae grow (Smits and Wallander, 2017). Fungi can generate adhesive forces at their hyphal tips on contact with the mineral surface, producing significant osmotic pressure. The forces at the mineral surface together with the large internal hyphal pressure (0.4 to 1 MPa) (Martino and Perotto, 2010) can mechanically break down minerals. Mycorrhiza may cause the formation of tubular pores on minerals by either dissolution processes, and the newly created pores may weaken the minerals’ physical strength and promote further penetration of hyphae (Martino and Perotto, 2010). Bacteria also promote physical weathering but their contribution has been studied much less than that of fungi.

In general, physical weathering processes, either abiotically or biotically induced, increase the specific surface area of minerals by creating fractures and increasing pores, cracks, and surface roughness. Increased mineral surface area, in turn, promotes accelerated abiotic and biotic chemical dissolution and microbial colonization.

Chemical aspects

Modes of microbially-mediated chemical weathering can be placed into three categories: change in pH, chelation (ligand-promoted dissolution), and redox reactions (Samuels et al., 2020). Together with physical weathering, they are depicted in Fig. 4. Microbially mediated weathering can (i) cause structural changes in minerals or dissolve them, (ii) provide nutrients to microbes and plants, (iii) sustain microbial energy demands (electron transfer reactions), and (iv) promote secondary mineral formation.

Protons and negatively charged ligands released either during microbial processing of organic substrates or direct secretion, in particular of low-molecular-weight organic acids (LMWOA), can cause the dissolution of minerals (Fig. 5). Microbially mediated proton production can be induced by ammonium oxidizers (e.g., after N fertilizer application) and Fe oxidizers (e.g., at redox fluctuating zones). Ligand-promoted dissolution starts with metal complexation or chelation by various biomolecules (chelators). In addition to the compounds produced during incomplete oxidation of organic substrates, microbes (and plant roots) secrete numerous LMWOAs, such as oxalic acids, citric acids, amino acids, and phenolic acids, which all are effective complexing agents (chelators). Siderophores are specific chelators that selectively complex ferric ions (Fe(III)). Complexing agents can bind directly to the metals on the mineral surface, causing mineral dissolution. Complexation of metal ions by LMWOAs in solution reduces their activity and thereby accelerates mineral dissolution (Berenjian and Seifan, 2022).

The EPS and biofilms that cover mineral surfaces can drive chemical and physical mineral weathering. Due to their diverse composition, EPS can hinder or accelerate the dissolution of minerals. They mediate metal transport and availability by sorption, complexation, redox cycling, particle trapping, and biomineralization. While neutral EPS components (e.g., sugars, starch, cellulose, xanthan) have no effects on mineral dissolution (Tourney and Ngwenya, 2014, the references therein), acidic EPS components dissolve minerals by complexation of metals or by lowering pH (Samuels et al., 2020). Since EPS is mostly negatively charged, it binds with and accumulates cations, which might result in the neoformation of minerals (Berenjian and Seifan, 2022). In addition, EPS can act as an electron acceptor or donor (Flemming and Wingender, 2010).

Microbes on the surfaces or in the vicinity of minerals may utilize minerals as electron sinks or sources in redox reactions. The mineral redox reactions are coupled with half reactions that provide nutrients, generate energy, or prevent toxic effects for microorganisms (Chorover, 2022). Oxidation of reduced metals (e.g., Fe(II), Mn(II)) present in mineral structures may serve as energy sources in C- and nutrient-poor environments, such as regolith and at the soil–rock interface. Microbially oxidized metals can undergo nucleation and subsequently secondary mineral precipitation on minerals, microbial cells, and EPS (Chorover, 2022). In addition, redox reactions either produce (oxidation) or consume (reduction) protons, and thereby affect proton-driven weathering.

Microbially-mediated mineral (trans)formations can alter soil physical and chemical properties as well as soil development pathways. For example, mineral weathering by ectomycorrhizal (EM) fungi contributes to podzolization by dissolving Al in upper horizons (van Schöll et al., 2008). Bacteria may help EM fungi or even dominate the weathering process by producing LMWOAs

Fig. 5 Microbially-induced mineral weathering pathways. At the microbial–mineral interface, elements within the mineral structure are released by different microbially-mediated processes: proton-induced dissolution, complexation with ligands, and oxidation/reduction. Physical weathering may support the chemical weathering. The elements released are either taken up by microorganisms and plants or precipitate to form secondary minerals such as phyllosilicate clays as well as Fe, Mn, and Al hydrous oxides.

(Lambers et al., 2009). However, only certain types of bacteria and fungi control the weathering of specific minerals. Removal of K^+ from primary phyllosilicate minerals (i.e. mica and chlorite) by bacteria and fungi support their transformation into expandable clay minerals such as vermiculite, and interstratified forms, and eventually the genesis of Vertisols. Fungi can alter the biotite interlayer spacing and promote both K^+ depletion and Fe(II) oxidation, causing the formation of vermiculite and Fe(III) oxide clusters (Bonneville et al., 2009). Iron-reducing bacteria induce the transformation of smectite into illite (Kim et al., 2004), while Fe-oxidizing bacteria can oxidize Fe(II) and dissolve Al and Si from illite, thus, promoting the neoformation of smectite (Zhao et al., 2017). Microbially-formed secondary Fe(III) and Mn(IV) minerals can serve as electron acceptors for heterotrophic respiration in oxygen-limited environments (Chorover, 2022). The alteration and neoformation of clay minerals and hydrous metal oxides can modify soil physical properties (e.g., porosity, water and gas permeability) and control soil fertility by adsorption–desorption reactions and stabilization of soil OM. Microbially-mediated transformation of minerals is therefore a crucial component of soil and ecosystem development.

Element cycling

Microbially-mediated weathering makes rock-derived elements available to biota, and thereby fuels biogeochemical cycles. All essential elements for microbes and plants, except for those present dominantly in water and air (i.e., H, C, N, O), derive from rock (Table 1). Nutrient elements released from rock minerals will form precipitates, leach downward, or become incorporated in plant and microbial biomass, and are re-released during microbial breakdown of plant debris and microbial necromass. The re-cycling of OM-bound nutrients is of increasing importance as soils deplete in rock mineral sources with progressing ecosystem development and pedogenesis. Since OM interacts with minerals, much of the OM turnover and related element cycling in soils is linked to microbial–mineral as well as mineral–OM–microbial interactions.

Table 1 Examples of rock mineral sources of essential nutrients to microbes in soils.

Elements	Minerals
K	feldspar (microcline, orthoclase), mica (biotite, muscovite), illite, smectite (saponite, montmorillonite)
Ca	feldspar (anorthite), apatite, smectite (saponite, Ca-montmorillonite), calcite, pyroxene
Mg	mica (biotite), smectite (saponite), chlorite, sepiolite, phlogopite, palygorskite, dolomite, hornblende, olivine, pyroxene, amphibole
Fe	mica (biotite), chlorite, sepiolite, lizardite, olivine, pyroxene, amphibole, pyrite
Mn	pyroxene, amphibole
P	apatite, hydroxyapatite, strengite, variscite
S	pyrite, chalcopyrite

Si is not classified an essential nutrient.

The vast majority of soil microbes gain energy from organic substrates that ultimately originate from plant photosynthates. The entry of plant-derived OM into the soil system involves OM–microbe interfacial reactions, such as microbial colonization on plant litter surfaces. Depolymerization of plant-derived macromolecules that requires the binding of extracellular enzymes to their target biomolecules (e.g., cellulase to cellulose), is often the rate-limiting step in OM decomposition processes. Despite this, our understanding of how heterotrophic bacteria and fungi colonize and degrade the surface of plant-derived OM in soil is limited to the fungal degradation of wood. Microbial metabolites and residues, especially bacterial and fungal cell wall fragments (Miltner et al., 2012), together with plant-derived compounds, are the major components of OM in soils (Sokol et al., 2019). Due to microbial decomposition, the OM entering soil decreases in molecular size and becomes increasingly oxidized. The increasing number of oxidized functional groups (e.g., carboxylic and phenolic groups) allows for various sorptive interactions with mineral surfaces. These interactions with minerals tend to slow down microbial decay and thus enhance the persistence of soil OM and retention of the OM-bound elements (i.e., C, N, P, S).

While mineral-bound OM is relatively stable, it can be re-mobilized by plant- and microbially-secreted organic ligands or by electron shuttling (see “Chemical aspects” above), allowing C, N, and redox-sensitive metals to cycle in the ecosystem. The oxidation of reduced elements including organic C is coupled with the reduction of other elements. Under O₂-limited conditions, as in waterlogged soils, oxidized metals (i.e., Mn(IV) and Fe(III)) in minerals may then serve as electron acceptors of heterotrophic respiration. The reduction of these metals promotes the dissolution of their host minerals. Organic and inorganic forms of elements bound to or co-precipitated with Mn(IV) and Fe(III) hydrous oxides would be re-dissolved and available for biota by the reduction of these secondary minerals.

Contribution to soil aggregate formation

Another consequence of mineral–OM–microbial interaction is the clustering or aggregation of soil organic and inorganic particles. Microbial cells and extracellular polymers can bind strongly to mineral surfaces, and microbially-mediated mineral weathering promotes the formation of nano-sized secondary minerals featuring large specific surface areas and reactivities (see above). These organic and mineral particles interact strongly with each other in non-random ways to form composite particles, so-called aggregates.

An intriguing example of the formation of such structural units at the micro scale is the intimate association of bacteria with their metabolites and exudates, and nano-sized minerals, as revealed by transmission microscopic observation of soil thin sections (Fig. 6A and B). Such bacterial microaggregates encrusted by EPS-clay coatings may form within weeks at the suspension–solid interface (Lünsdorf et al., 2000). Nano-sized, secondary Fe hydrous oxides as well as short-range-ordered aluminosilicates can precipitate on negatively charged surfaces of microbes and EPS (Chorover, 2022). Clay coatings on fungal hyphae, bacterial cells, or microcolonies have been observed in soil thin sections, often embedded in EPS. Their thickness varies between 0.1 and 1 µm (thicker on hyphae) and the clays tend to be reoriented in parallel to the microbial surfaces (Chenu and Cosentino, 2011). Such coatings may be advantageous against desiccation and predation with the tradeoff of reduced diffusion of oxygen, enzymes, and substrate (Chenu and Cosentino, 2011).

At a slightly larger spatial scale, particulate OM (POM), representing plant debris, is often covered with nano- to micron-sized minerals (Fig. 5C), which can result from colonization by heterotrophic microbes that degrade POM. Such POM–microbe–clay interaction may serve as starting point for the occlusion of POM into larger aggregates (Golchin et al., 1997). Then the degradation of occluded POM is strongly controlled by the aggregate pore structure (Schlüter et al., 2022).

Microbial interfacial interactions can contribute to the formation and stability of soil aggregates by several mechanisms. Extracellular polymers (e.g., EPS) and microbial biomass itself (e.g., hyphae, necromass) can cause and enhance inter-particle cohesion. Extracellular polysaccharides with high molecular weight (10⁵ to >10⁶ Da) and the capability to form intermolecular linkages are most effective for inter-particle cohesion (Chenu and Cosentino, 2011). The hyphal network of fungi and actinobacteria can effectively entangle and interlink soil particles. Controlling factors include the strength of adhesion at the hyphae–particle contact point, hyphae tensile strength, hyphae spatial distribution, and fungal taxonomic group (Chenu and Cosentino, 2011). Fungal hydrophobin (section “Cell surface structure”) enhances water repellency and, thus, aggregate stability against water dispersion.

Fig. 6 Examples of aggregation as consequences of microbe–organic matter–mineral interfacial reactions. Transmission electron microscope images of bacterial microaggregates observed in thin sections of (A) an intact soil (Robert and Chenu, 1992) and (B) water-dispersible clay (Chenu and Plante, 2006). (C) SEM image of decaying plant detritus with clay coatings on its surface (C').

On the other hand, soil microbes promote disaggregation as most soil microbes actively degrade OM to gain energy and to obtain nutrients. Even the enzymes present in EPS can reduce aggregate stability (Kaur et al., 2022, and references therein). Organic compounds, therefore, can serve as substrates or aggregate binding agents. At the macro-aggregate scale, the input of plant-derived OM into soil appears to control macroaggregate formation and the microbial contribution is rather passive. This is evident from the frequently observed breakdown of macroaggregates with the reduction of OM input in agricultural soils.

A fundamental soil feature arising from the adhesion and clustering of organic and inorganic particles is the formation of pores, the void spaces between those particles. It is these pores or along their walls where solid–water–gas interfacial reactions take place. Connected pores (i.e., pore network) provide the flow path for water and gases, as well as providing habitats for soil microbes, micro- and meso-fauna, and plant roots. The chemical and physical changes that take place with the interfacial interactions of OM, minerals, and microbes, therefore, have profound consequences on biogeochemical cycles and pedogenesis (Chorover, 2022).

Outlook

Starting from the different mechanisms of microbial attachment to mineral surfaces, we have elaborated three fundamental consequences of microbe–OM–mineral interfacial reactions taking place in the soil, namely mineral weathering and transformation, elemental cycling, and formation of structure. Once a rock is exposed to the surface of the Earth, mineral surfaces are prone to initial microbial attachment and colonization. With the activities of these first colonizers (e.g., Fe oxidation), secondary minerals start forming, and rock-derived elements begin to be available via weathering, providing more extensive surfaces and nutrients to support microbial and plant life. The secondary minerals then bind strongly to OM, forming metastable OM-mineral agglomerates that feature both mineral and organic surfaces. Due to the heterogeneity of the surface chemistry (and physical structure), the neoformed mineral and organo–mineral phases provide habitats for more diverse microbial communities and plant roots. With these feedback loops (microbes create new surfaces and these surfaces allow more and other microbes to colonize), microbe–mineral surface interactions drive pedogenesis and ecosystem development toward greater diversity and complexity. Therefore microbe-mediated weathering, element cycling, and porous structure formation are essential components of pedogenesis and soil functioning.

Despite the knowledge accumulated so far, our current understanding of microbe–mineral interfacial interactions still appear incomplete. Open research questions that might be worth exploring further in the future include

- Colonization of mineral surfaces: Are biofilms common in soils? Is their occurrence constrained by certain physical conditions and microenvironments? How do they form and are they confined to specific microbial communities? How stable is the attachment of biofilms on the surfaces?

- Weathering: Are there antagonistic, synergistic, and successive effects of bacteria and fungi in the destruction of primary and the formation of secondary minerals? Is it mostly mycorrhizal fungi that initiate the weathering process, or is the contribution of bacteria rather underestimated? What are the individual controlling factors of bacterial and fungal weathering?
- Element cycling: How does microbe–OM–mineral attachment relate to stabilization and destabilization of OM? Or more precisely, what controls the balance between stabilization and destabilization? Is it linked to the type of mineral, chemical conditions, and localization (i.e. rhizosphere vs. bulk soil)?
- Structure formation: While the role of microbe–mineral interfacial interactions in the formation of nano- and micro-scale structural soil units is well recognized, it remains unclear if these effects extend to the macrostructure of soil. To what extent and how does the porous, hierarchical soil structure account for soil microbial diversity? What are the dominant factors controlling the formation of micro- and macro- structures?
- Consequences of microbe–mineral surface interactions: To what extent, do microbemineral interactions control the rate and trajectory of pedogenesis and ecosystem development? Does the contribution change with the stages of pedogenesis and ecosystem development? What is the contribution of microbe–mineral interactions to soil processes relative to those induced by plants?

Answering these questions will not only add to the knowledge on surface interactions in soil but might also add much to the emerging understanding that soils form, develop, and function in more direct responses to microbial life.

Abstract

Pesticide molecules in soils undergo different processes of biological, physical and physico-chemical origin, and occurring over different time (minutes to decades) and spatial (nm to km) scales. Pesticides are represented by a diversity of molecules having contrasting physico-chemical properties inducing various kinds of behavior in terms of persistence, sorption, transport with the potential for contamination of water, uptake by plants, and possible impacts on soil biota and microbial processes. This chapter proposes an update of current available knowledge on the main processes and current state of the art of knowledge integration in pesticide fate models at the plot and watershed scales for environmental risk assessment.

Key points

- The behavior of most pesticide is controlled by their molecular properties and the soil characteristics.
- Individual processes are interdependent due to their coupling in time and space.
- This coupling is driven by local pedoclimatic conditions related to composition of the soil solution and soil particles, soil porosity determining microhabitats for degrading microorganisms and accessibility to reactive sites.
- Significant progress has been made to represent spatially the main soil processes at the landscape scale and to integrate the different routes for environmental contamination or exposure.
- Although used for regulatory risk assessment, process-based models still have difficulties in describing some processes such as particulate and colloidal transport, the formation or release of non-extractable residues.
- Other limits of currently used models are related to the poor representation of diversified cropping practices and cropping successions (pluri-annual) and the feedback loops on soil processes.

Nomenclature

c	Concentration
DT_{50} , DT_{90}	Disappearance time (50%, 90%) (days)
K_H	Henry's Law constant (dimensionless)
k	First-order degradation rate constant (day^{-1})
K_d	Sorption coefficient to soil (liters per kilogram)
K_{oc}	Sorption coefficient to soil organic carbon (liters per kilogram)

K_{om}	Sorption coefficient to soil organic matter (liters per kilogram)
K_{ow}	Octanol/water partition coefficient (dimensionless)
T	Temperature (Kelvin)
t	Time
$t_{1/2}$	Half-life (days)
VP	Vapor pressure (Pascal)
WS	Water solubility (moles per liter)

Introduction

Synthetic organic pesticides have been used widely since the late 1940s to increase crop yields in agriculture. Though strict registration criteria have led to a ban on the use of many older compounds, such as organochlorine insecticides, several hundred active ingredients still remain available. With different regulations according to countries and continents, several compounds, now banned in the European Union (EU), are still used in USA, Latin-America, China or Africa. In the EU, for example, more than 450 of approximately 850 formerly approved compounds are still marketed. Pesticide contamination occurs in most environmental compartments (water, air, soil, living organisms) and has potential impacts on the environment and human health. Despite restrictions on use and some product withdrawals, pesticide residues can be detected for several years in the environment, and soils play a key role in the long-term fate of these agrochemicals.

The soil is the ultimate sink for a large part of the pesticide that is applied to crops. Non-agricultural uses may still exist but in other cases have been banned, depending on countries and current regulations. Nevertheless, agricultural uses are the major sources of pesticides in the environment. Compounds such as nematicides (for control of plant-parasitic nematode worms) are usually incorporated into the topsoil. Many herbicides used in arable crops are applied either to bare soil prior to emergence of the sown crop or to the seed bed immediately post-germination, and so most of the compounds reach the soil surface directly. In contrast, insecticides and fungicides are usually applied later in the season when the crop may have closed its canopy, and so most compounds will be intercepted by the crop foliage; even so, some spray will drift downward, and wash-off by rain may subsequently move more compound to the soil. The rates at which pesticides are applied vary widely: according to the FAO, European agriculture consumed an average of 3.1 kg ha^{-1} in 2018, with considerable variation from more than 8 kg ha^{-1} in the Netherlands and Belgium, to less than 1 kg ha^{-1} in Scandinavia and the Baltic countries.

To understand the behavior of so many diverse compounds in the environment, it is necessary to develop an overarching framework of understanding based on the physicochemical properties and behavior of each compound. Important aspects of pesticide behavior in soil to be considered are persistence, sorption, transport with its potential to contaminate water, uptake by plants, and possible impacts on soil biota and microbial processes.

Physicochemical properties of pesticides

Water solubility, WS, plays an important role in the fate of pesticides in the environment as one of the routes of pesticide transport within the soil or between water and other environmental compartments is water. The water solubility of pesticides was shown to be mainly related to the nature of the surface and volume of molecules, to their branching, and to their polarizability (which can be related to the volume) (Mamy et al., 2015).

The octanol-water partition coefficient, K_{ow} , is the most frequently used parameter to characterize the hydrophobicity (or lipophilicity) of chemicals, which is a very important property in the environmental sciences. It was demonstrated that the K_{ow} of pesticides depends on the volume of the molecule, its branching, the polarizability, the dipole moment, the energy of the highest occupied molecular orbital, and energy of the lowest unoccupied molecular orbital (Mamy et al., 2015).

The dissociation constant, pK_a , which describes the extent to which a compound dissociates in solution, is a fundamental physical property of a chemical. It is a key feature that governs the chemical reactivity of the pesticides with other compounds in any solvent, and also interaction with the solvent itself, and thus its hydrophobicity and water solubility. Mamy et al. (2015) showed that the pK_a of organic compounds were related to the charges of the molecule and to the energy of the highest occupied molecular orbital.

The vapor pressure, VP, and the Henry's law constant, K_H , are involved in the fit between physico-chemical properties and volatilization potential of compounds when considering pesticide volatilization from leaves and from soil, respectively. The VP is an indicator of the volatility of a pure chemical compound, and depends exponentially on the temperature. The K_H measures the partitioning of a chemical between two phases, air and water. Chemicals with low K_H will tend to stay in the aqueous phase, while those with high K_H will partition more into the gaseous phase. Air and water are major compartments of the environment, and water is considered to act as a vector among air, soil, sediment, and biota, therefore, knowledge of K_H is important in assessing environmental risks associated with a chemical. Polarizability and connectivity indices are good molecular properties to explain the vapor pressure range of organic compounds, but no particular property appeared to be more relevant than another to estimate K_H (Mamy et al., 2015).

Sorption and mobility in soil

Sorption

The sorption of pesticides in soils is a combination of the adsorption process, which is the passage of a solute from an aqueous phase to the surface of a solid adsorbent, and of desorption, which is the reverse process. According to the properties of solutes and substrates, several interaction mechanisms with the surface are possible: ion exchanges, interactions with metallic cations, polar interactions, charge transfers, and London-van der Waals forces/hydrophobic effect (Calvet, 1989). The greater is the pesticide sorption, the lower is its mobility and hence the risks of groundwater contamination. However, transport of adsorbed solute may also occur when adsorbing particles are displaced with the vertical migration of dispersed clays in the soil profile or through horizontal migration toward surface waters because of runoff or erosion (see below). The sorption of pesticides in soils is usually characterized by distribution coefficients between soil and soil solution according to various models such as the linear (K_d , L kg⁻¹) or the Freundlich ones (K_f). A high value for these coefficients indicates strong sorption. The sorption of pesticides depends on the molecular properties of the compounds, the soil properties, environmental conditions, and residence time in soils.

The sorption of pesticides in soils increases with the molecular volume of the compounds and with their branching (Mamy et al., 2015). It also depends on the ionization of the molecule (for example, cation sorption is high on negatively charged surfaces such as clay or humic substances), and on the hydrophilic or hydrophobic properties of the compound (sorption decreases when WS increases because the pesticide will have a greater affinity for the liquid phase). However, glyphosate for example, is a strongly adsorbed compound despite its strong water solubility because sorption of this herbicide (having four pK_a) involves high energy ionic bindings that counterbalance the effect of WS. Finally, the electronic structure of the molecule plays an important role in the sorption through polarity, the polarizability and charge delocalization (Calvet, 1989; Chaplain et al., 2011). It has to be emphasized that the surfactants of commercial products may change the sorption of active substances in soils (Beigel et al., 1998).

Organic matter (OM), and especially humic substances have strong chemical reactivity and are often the main adsorbents of pesticides. Clay minerals, oxides and hydroxides, however, may also be involved in adsorption (Calvet, 1989). In general, sorption increases with soil organic matter (OM) content, except for ionic compounds for which soil pH is the main determining property (Fig. 1, Barriuso and Calvet, 1992). Soil structure (bulk density, pore geometry), which also depends on agricultural practices and climate, influences pesticide sorption: for example, in conservation agriculture (low or no-till practices), OM accumulation on the soil surface favors the retention of pesticides (Alletto et al., 2010). Finally, pesticide sorption shows horizontal and vertical spatial variabilities due to the variation in soil properties (Chaplain et al., 2011).

Soil water content determines the retention of pesticides as it favors their transport toward the adsorption sites. In addition, when the soil water content increases, the OM becomes more hydrophilic which increases the sorption of hydrophilic pesticides. It was also demonstrated that the sorption of pesticides decreases when the soil temperature increases (Calvet, 1989).

The residence time of pesticide residues in soils changes their sorption properties through diffusion in the microporosity, physical entrapment and degradation (Barriuso et al., 2008). In general, a large increase in retention with time is observed for weakly adsorbed pesticides while for strongly adsorbed and persistent pesticides, sorption decreased with time or remained stable, and K_d does not vary with time when the pesticide's half-life is higher than 30 days (Fig. 2, Mamy and Barriuso, 2007).

Mobility and transport

Pesticides that arrive in soils can be transferred toward water and air. The transfers result from transport processes (molecular diffusion, advection/dispersion) coupled to sorption and degradation processes (Calvet, 1989). The main processes of transfer are runoff and erosion toward surface water, leaching toward groundwater, and volatilization toward the atmosphere. The relative extent of each process depends on the pesticide and soil properties, on the application methods, climatic conditions, and agricultural practices.

Transfer toward surface water

At the watershed scale, surface waters are streams, ponds, and ditches. Pesticide transfers occur in solute and or particulate phases. They are mainly controlled by climate, soil and pesticide properties, and agricultural practices.

Among the various climate characteristics, the intensity and duration of precipitation will strongly determine pesticide transfer toward surface water. Rain intensity can cause runoff when the speed of water supply exceeds the soil infiltrability, which is aggravated by long rain events. The date of the rain event compared to the date of pesticide application will also be decisive for transfer.

The soil slope is one of the key factors governing pesticide transfer toward surface water. When the slope increases, runoff speed increases so that erosion and the thickness of soil affected by erosion increase. The controlling soil characteristics are the presence of a weakly permeable soil layer, structural stability of the soils, and OM content which influences the structural stability. Finally, the soil water content is also crucial: if a rain event occurs when the soil is water saturated, water accumulates at the soil surface leading to runoff or to standing water depending on the slope.

Pesticide transfer depends on the physicochemical properties of the substance (WS, adsorption), and on the formulation of the plant protection product (for example, wettable powder and liquid formulations favor transport). They also depend on the

Fig. 1 Principal component analysis showing correlations between sorption coefficients K_d of three herbicides (atrazine, terbutryn and 2,4-D), organic carbon content and soil pH for surface horizons from different soil types; the two figures at the bottom highlight the relations between K_d and soil pH for a weak acid (2,4-D), and soil organic C for non-ionic and weak bases (atrazine, terbutryn). Fig. 2 Sensitivity analysis of the relationship between K_d and time as a function of pesticide half-life (days). From Mamy L and Barriuso E (2007) Desorption and time-dependent sorption of herbicides in soils. *European Journal of Soil Science* 58: 174–187.

amounts applied, and on the location of the pesticide in the soil (the risk of transfer strongly decreases if the pesticide is incorporated into the soil).

Maintaining plant cover or cropping residues (conservation agriculture) at the soil surface increases OM content leading to better soil structural stability and aggregate cohesion and a strong decrease in soil erosion. The presence of grass strips at the edges of fields favors pesticides adsorption and limits the amounts that could be transferred by runoff and erosion. Finally, irrigation may help to prevent runoff by maintaining an acceptable soil water content.

Transfer toward groundwater

Pesticides can reach groundwater through leaching, by vertical transfer in the dissolved phase, or through particulate transfer. The transfer mainly depends on pesticide sorption, soil properties and structure, and on the agricultural practices.

Numerous results have shown a close relationship between the depth of pesticide leaching and their sorption coefficients (Calvet, 1989). In general, the greater is the sorption, the less is the leaching. However, adsorbed pesticide may move vertically in the particulate phase (colloid facilitated transport).

The leaching of pesticides depends strongly on the soil structure which is heterogeneous and may show preferential pathways due to cracks (clay soils) or earthworms burrows, for example. Infiltrated water moves rapidly through macropores leading to limited contact with the adsorbing surfaces and to pesticide transfers at depth.

In conservation agriculture, the decrease in soil tillage favors the presence of macropores leading to a high risk of pesticides leaching (Alletto et al., 2010). On the contrary, the addition of organic amendments to compensate for the loss of soil fertility results in a decrease in vertical pesticide transfers.

Transfer toward the atmosphere

It is commonly accepted that volatilization, ranging from 0.1% of the applied pesticide dose to several tens of % under certain conditions, occurs after application from a few days to a few weeks for some compounds. However, the state of knowledge on the volatilization process is based on a relatively small number of datasets (fewer than 50 datasets have been acquired in the field on volatilization from soil) from studies developed since the 1990s, but that have been carried out with a diversity of methods. Moreover, the existing studies concern some compounds which are now banned or not widely used.

Volatilization depends on temperature and soil water content. Although an increase in temperature generally leads to an increase in volatilization, this effect may be limited by soil drying conditions, a common phenomenon at the soil surface, which may lead to an adsorption of the compound from the gaseous phase to the soil for certain compounds, thus limiting their volatilization. This sorption process occurs in addition to those presented in the previous section. García et al. (2014) took this process into account when modeling pesticide volatilization from bare soil to improve the description of diurnal dynamics. This process also explains the increase in S-metolachlor volatilized after 5 days with the increase in soil moisture at the time of application. This was observed by Prueger et al. (2017) through experiments conducted over 13 consecutive years. It should be noted that this effect cannot be predicted for all pesticides because the gas/soil adsorption coefficient is not available for all compounds, and the prediction of the soil water transfer under dry conditions remains a challenge.

The vapor pressure of a compound is the first indicator of its volatilization potential (see previous section). However, as compounds interact with the soil matrix, other characteristics have an indirect effect on the volatilization process, such as WS, K_{oc} and DT50. The estimated values of VP, K_H or WS can vary considerably depending on the method of determination used. This variability is important because it leads to uncertainty in the volatilization flux predictions.

In addition, the commercial formulation of the pesticide may also have an effect on the volatilization process. Houbraken et al. (2018) stated that effective vapor pressures of formulated compounds are the most appropriate values to be used in pesticide fate models. Das and Hageman (2020) estimated the soil-air partition coefficients of chlorpyrifos, pyrimethanil and trifluralin, formulated or not, and with the addition of adjuvants. They found that, under the conditions tested, formulated compounds may undergo greater volatilization than the active ingredient alone but they also indicated that these results can be contradictory depending on temperature.

The presence of a mulch can have a strong effect on volatilization by (1) increasing the exchange surface with the atmosphere (which tends to increase transfers), (2) modifying the temperature and humidity conditions and (3) modifying the availability of the pesticide to transfers, depending on whether or not it is adsorbed onto the mulch or degraded. However, prediction of the effect of mulches on volatilization is still uncertain (Bedos et al., 2017). Few data sets exist and the corresponding studies present contradictory results: an increase in volatilization in the presence of mulch but also the reverse effect, i.e. a reduced volatilization after rainfall as reported by Bedos et al. (2017). These authors based their study on the effect of the presence of a mulch on the volatilization dynamics of S-metolachlor and recommended to characterize better interception of the compound by the mulch at the time of application, modification of the surface conditions in the presence of a mulch, and finally its sorption/degradation in the mulch.

Incorporation of the pesticide into soil has been identified as a way to limit volatilization and photodegradation. Quantification of the effect of this practice on the volatilization of trifluralin applied to bare soil and incorporated into the soil 24 h after application, showed a decrease in the rate of volatilization by two orders of magnitude (Bedos et al., 2019).

Persistence in soil

The degradation of pesticides is one of the key processes of their fate in soil because it controls their removal from the environment. Degradation is due to numerous chemical transformations which change the composition and structure of the molecules. Degradation can be biotic or abiotic and several intermediate compounds (degradation products or metabolites) can be produced between the initial molecule and the final mineral ones. When the pesticide is transformed to a mineral molecule, such as CO_2 , it is fully eliminated (this is mineralization). Most of the time, degradation follows first-order kinetics, allowing the degradation half-time (DT_{50} ¹ days) to be calculated. The higher is the DT_{50} , the higher is the pesticide persistence in the soil. However, the degradation kinetics can also be bi-phasic or present a lag phase.

Abiotic degradation

Abiotic transformations are due to chemical reactions that are not catalyzed by enzyme systems. They include hydrolysis, oxidation–reduction, and photochemical reactions.

Hydrolysis and oxidation-reduction reactions occur in solution. The reaction kinetic depends on the ionic composition of the medium, in particular pH and metal cations, on the nature of adsorbing phases, and on the temperature. The most favorable physicochemical conditions for reduction reactions are found in hydromorphic soils. The electrons sources come from sulfides, reduced metals, or organic compounds originating from OM or microorganism activity. Oxidation reactions are less known, but they seem to be favored by adsorption on clay minerals and metal oxides (Chaplain et al., 2011). The hydrolysis and reduction reactions of pesticides depend on pesticide quantum molecular properties such as the energy of the lowest unoccupied molecular orbital, while the highest occupied molecular orbital is the most useful pesticides molecular property to estimate their oxidation in the environment (Mamy et al., 2015).

Pesticide molecules can absorb a part of the light energy (UV and visible) they receive. The formation of an excited state through the absorption of a photon allows the molecule to be transformed or to interact with other molecules. Photochemical reactions may degrade pesticides by two types of processes: direct photolysis and indirect photodegradation. In direct photolysis, the pesticide itself absorbs light energy, becomes excited and, depending on the reaction activation energy, may undergo a transformation reaction. Indirect photodegradation is defined as the reaction of a ground-state pesticide with another photochemically produced species. Both reactions occur mainly in the dissolved phase when the pesticide is in the liquid phase of the soil, but also in the adsorbed phase if it is exposed to light. Consequently, photolysis or photodegradation reactions depend on the soil characteristics (especially porosity) but also on the climate, time of day, season, latitude, altitude, and atmosphere. In the liquid phase, degradation kinetics vary with pH, the presence of a solid phase or the presence of dissolved or suspended substances (Chaplain et al., 2011). Indirect photodegradation is favored when the soil water content is high while direct photolysis is more important in dry soil because light penetrates more easily. Agricultural practices also play a role, for example through the addition of organic amendments that add humic substances to the soil: humic substances tend to decrease direct photolysis through light screening, static and dynamic quenching. The most relevant pesticide molecular properties to explain the variability of photochemical reactions of organic compounds are the energy of the lowest unoccupied molecular orbital and energy of the highest occupied molecular orbital, molecular weight, polarizability and dipole moment (Mamy et al., 2015). Finally, it should be noted that pesticides that are intercepted by plants are on the leaf surfaces, and may also be subjected to photochemical reactions.

Biotic degradation

Biotic degradation is the main degradation mechanism of pesticides. It is due to the action of various organisms (mainly bacteria and fungi but also algae and protozoa) and results from chemical transformations by enzyme systems, which require the pesticides to be dissolved in the soil liquid phase. Pesticide biotic degradation can result from three actions by microorganisms: direct metabolism (the pesticide is used as an energy source by microorganisms), co-metabolism (the organisms grow at the expense of a co-substrate to transform the pesticide without deriving any nutrient or energy for growth from the process), and synthesis (conjugation and oligomerization). The final step of pesticide biodegradation is mineralization. If the microorganisms do not possess all the enzymatic equipment to mineralize pesticides, metabolites are excreted into the soil and can be used by other microorganisms. The biotic degradation of pesticides in soils depends on physical, physicochemical and biological factors, together with pesticide properties and agricultural practices.

The main physical factors influencing the biodegradation of pesticides are soil temperature and water content which depend on the climate. In general, biodegradation increases with soil temperature to a limit that is compatible with microbial activity. The optimal water content for aerobic microbial activity is close to field capacity. Soil structure also plays an important role by favoring, or restricting, the circulation of water and air. For example, compaction from farm traffic and soil tillage leads to changes in soil physical properties such as a decrease in porosity, oxygen content and water infiltration that can change the biological functioning of soil and create anaerobic conditions. Soil texture, pH, OM content, and redox potential have an effect on pesticide degradation because they influence their sorption (pesticides have to be in the liquid phase to be degraded) and the activity of microorganisms.

¹ DT_{50} values correspond to degradation but often include other processes involved in the disappearance of the compounds and in that case DT_{50} is the dissipation half-time.

The biodegradation of pesticides depends on the microorganisms' specificity (some pesticides can be degraded by a high diversity of microorganisms in contrast to others), on their adaptation (see below), and on their spatial heterogeneity (microbial biomass is often higher at the soil surface than in the deeper soil layers, and degradation tends to increase when the sizes of soil aggregates increase) (Vieublé-Gonod et al., 2003). The spatial variability of mineralization at the aggregate scale is very large (Fig. 3).

The molecular properties of pesticides control the ability of microorganisms to degrade a compound. In general, degradation decreases when the molecular weight, the branching and or the number of halogen atoms of the molecule increase (Mamy et al., 2015).

Agricultural practices based on monoculture favor repeated applications of the same pesticides that induce adaptation of the microflora resulting in the accelerated degradation of pesticides. The decrease in soil tillage in conservation agriculture, leading to the accumulation of OM at the soil surface, has contrasting effects on pesticide degradation (Alletto et al., 2010): competition between pesticide retention on the mulch (decreasing the bioavailability) and microbial degradation can decrease degradation but, conversely, the presence of OM can stimulate the microbial activity which favors pesticide degradation. During pesticide degradation, the formation of non-extractable residues is frequently observed. It can be considered a stabilization process that is responsible for pesticide immobilization in the soil (Fig. 4).

Pesticide non-extractable (bound) residues

All pesticides arriving to the soil form non-extractable (bound) residues (NER) (Gevao et al., 2000). The NER represent compounds in soils which persist as the parent substance or its metabolite(s) after extraction; the extraction method must not substantially change the compounds themselves or the soil structure. The proportion of NER is operationally defined by the extraction procedure employed, and this can also indicate the mechanisms involved in their formation: residues strongly sorbed or entrapped, covalently or biogenically bound residues derived from biotic degradation and incorporated into the microbial biomass (Kästner et al., 2014). For most pesticides, the formation of NER is usually correlated to the soil's biological activity and to the amount of OM in the soil.

A comprehensive review of the pesticide registration data showed that about 50% of the pesticides exhibit a low proportion of NER (less than 30% of the initial amount) while only 12% of pesticides have a proportion of NER that exceeds 70% (Barriuso et al., 2008). The largest proportion of NER was found for carbamates, and in particular for dithiocarbamates. Organophosphates are the pesticides that form the least NER (Fig. 5). In general, pesticides or metabolites supporting 'free' reactive chemical groups, such as

Fig. 3 Spatial variability of 2,4-D mineralization at the mm aggregate scale. Adapted from Vieublé-Gonod L, Chenu C, Soulas G (2003) Spatial variability of 2,4-dichlorophenoxyacetic acid (2,4-D) mineralisation potential at a millimetre scale in soil. *Soil Biology & Biochemistry* 35: 373–382.

Fig. 4 A dynamic view of the main processes involved in pesticide sorption and degradation in soils.

Fig. 5 Classification of pesticide families according to their capacities to form non-extractable (bound) residues. Plotted data correspond to the proportion of NER formation reported in the EU assessment reports and concern experiments with a target duration of ca. 100 days. From Barriuso E, Benoit P, Dubus I. (2008) Formation of pesticide nonextractable (bound) residues in soil: Magnitude, controlling factors and reversibility. *Environmental Science & Technology* 42: 1845–1854.

aniline or phenol, tend to produce a larger proportion of NER. The degradation of pesticides that produce metabolites with hydroxyl or amine groups leads to an increase in NER formation by covalent bounding because their metabolites are more reactive than the parent compound (Benoit et al., 1999). The result of these different reactivities between the parent and its metabolites is a competition between degradation and the formation of NER. If the parent compound is involved in NER formation, then rapid degradation competes with NER formation. If, on the other hand, the metabolite is involved in NER formation, then rapid degradation may lead to considerable formation of NER. Pesticides with a large number of electronegative substituents, such as the halogens, tend to form fewer NER than compounds with a smaller number of substituents. This is an illustration of the importance of degradation pathways and intermediate degradation products on NER formation.

Most of environmental factors affecting biological activity, such as temperature or soil moisture content, are likely to have an influence on NER formation. There is therefore an apparent competition between pesticide mineralization and NER formation. In general, NER amounts increase with increasing water content until the soil reaches saturation, and also increase with temperature. The nature and the amount of soil OM also influence NER formation (Fig. 6). In general, an increase in OM content leads to an increase in NER, as demonstrated for compost additions. Frequently pesticides incubated on mulch or fresh organic matter resulted in a higher proportion of NER than those incubated directly in soils, and the increase in the humification degree of the plant residues increased the proportion of NER (Benoit et al., 1999).

Bioavailability and uptake by plants or earthworms represent only a small percentage of the total amounts of NER; the formation of NER leads to a decrease in the toxicity and bioavailability of pesticides. However, a proportion of NER could be released by different natural mechanisms: ionic modifications and the addition of N-ammoniacal fertilizers to the soil can induce a partial release of some NER.

Fig. 6 Hypotheses of formation of pesticide non-extractable residues by incorporation into soil organic matter during the humification process.

Soil column leaching experiments have demonstrated that NER are usually concentrated at the top of the column, indicating the poor leaching capacity of these residues. Although the bulk of residues was confined to the first few centimeters of the soil columns, it should be noted that their extractability decreased with depth and that significant proportions of NER remained at the bottom of the columns (Benoit et al., 2000). The exact origin of these NER deep in the column is difficult to establish. They could result from the leaching of NER formed near the soil surface, indicating an intrinsic or facilitated mobility, or from the formation of NER at various depths following leaching of the parent pesticide and its metabolites down the column.

In summary, gaining detailed information of how NER are formed and subsequently released is essential if they are to be included in environmental risk assessments. However, the explicit consideration of NER in environmental risk assessment would require more intensive long-term experiments. The formation of NER can be interpreted conceptually by flow mass using an approach based on kinetic compartment models including compartments involving different mechanisms of NER formation (Fig. 7, Kästner et al., 2014). The concepts of 'slow sorption' can be easily implemented in pesticide fate models through a kinetics approach. This slow sorption could evolve to an irreversible sorption pool by suppressing desorption from the slow sorption sites, or by adjusting equilibrium constants of these sites to high values, thereby creating 'restrictive sites' or sites with irreversible retention. The main issue with this kind of approach is the lack of information regarding the exact chemical nature of NER.

Effects on soil biota and uptake by plants

Uptake of pesticides by plants

Pesticides can be transferred to vegetation from the soil and or water by uptake through the roots (i.e., symplastic way), from the atmosphere by their aboveground parts after wet or dry deposition, or following rain-splash in which soil particles are dispersed on to leaf surfaces. For atmospheric contaminants, the predominant initial site of interception is the cuticle, where adsorption is the first step in the transfer of volatile and non-volatile organic compounds to the plant. The absorption of pesticides by plants was shown to be mainly driven by molecular properties related to the size of the compounds (branching and steric descriptors) (Mamy et al., 2015).

Fig. 7 Schematic diagram of abiotic and biotic non-extractable residues (NER) formation including microbial degradation of organic compounds in soil: Type I (sequestered) and Type II (covalently bound) NER are formed mostly by abiotic processes such as oxidation with reactive oxygen on catalytic surfaces, non-enzymatic hydrolysis or photodegradation on the soil surface, and finally sorption, entrapment, or covalent bonding to soil organic matter (SOM). In addition, these reactions may also be triggered by a microbial radical forming exoenzymes (e.g., laccases and peroxidases). With increasingly productive (biomass formation) biodegradation of the compounds, the relevance of bioNER formation also increases. BioNER formation by heterotrophic CO₂ fixation has to be taken into account if labeled CO₂ is produced during microbial degradation processes. Adapted from Kästner M., Novack KM, Miltner A, Trapp S, Schäffer A. (2014) Classification and modelling of nonextractable residue (NER) formation of xenobiotics in soil—A synthesis. *Critical Reviews in Environmental Science and Technology* 44: 2107–2171.

Effects on soil organisms (microflora and macrofauna)

The persistence of pesticide residues in soil is identified as a major threat for soil dwelling organisms that support many ecosystem services. Leading reviews of the literature have already addressed the effect of pesticides on soil organisms (Datta et al., 2016), including bacterial populations (Johnsen et al., 2001; Thiour-Mauprivez et al., 2019). Relevant ecotoxicological endpoints for terrestrial organisms (e.g., soil microorganisms, invertebrates such as earthworms and enchytraeids, and also other groups) that support a range of ecosystem services are lacking compared to aquatic organisms. The availability of ecotoxicological parameters is also less for chronic than for acute ecotoxicity endpoints.

Although authorities release pesticides to the market only after their careful and thorough evaluation, the risk assessment for soil organisms is unsatisfactory, particularly for microorganisms for which pesticide toxicity is considered solely by one global test measuring N mineralization (Thiour-Mauprivez et al., 2019). Literature on the effects of pesticides on soil microorganisms suggests that they have only minor or transient effects when they are applied at the recommended doses, but the corresponding processes and mechanisms are still poorly understood. The effects of pesticides on the soil microflora are of importance because many microbial functions are critical to crop production, soil sustainability, and environmental quality. Therefore, the structural and functional characteristics of microbial communities, when they can be measured, will represent indicators of choice for monitoring the impact of pesticides on soil ecosystems and for assessing their biological status. The relationships of the different structures of pesticides on the growth of various groups of soil microorganisms are not easily predicted. Some pesticides stimulate the growth of microorganisms, but others have depressive effects or no effect. For example, diflubenzuron can stimulate the activity of nitrogen fixation bacteria in soil, but methylpyrimitos decreases this activity. Information on microbial populations is obtained by culture-dependent methods. Many microorganisms cannot be cultured, therefore, progress in molecular methods and omics tools have opened up large possibilities.

Pesticides may harm soil organisms such as earthworms and enchytraeids, but there is a lack of knowledge on their relative sensitivity to these chemicals and the consequences for soil functions (Pelosi et al., 2021). Although there are several reports on the effects of pesticides on earthworms and enchytraeids (Datta et al., 2016; Römbke et al., 2017), traditionally ecotoxicology has paid little attention to the direct or indirect effects of pesticides on soil functions such as soil OM mineralization. Pelosi et al. (2021) have demonstrated that earthworms no longer promoted soil OM mineralization when fungicide was present at three-fold the recommended field rate. The effects of enchytraeids on soil OM mineralization were similar with and without fungicide exposure.

The treatment of crop seeds with insecticides and or fungicides, aimed at protecting seeds from pests and diseases, is widely used in conventional agriculture. During the growing season, fields often receive additional broadband herbicide applications. Despite this widespread use, little is known about potential side effects or interactions between these different pesticide classes on soil organisms. In a greenhouse pot experiment, Van Hoesel et al. (2017) studied single and interactive effects of seed dressing of winter wheat (*Triticum aestivum* L. var. Capo) with neonicotinoid insecticides and or strobilurin and triazolinthione fungicides, and an additional one-time application of a glyphosate-based herbicide on the activity of earthworms, soil microorganisms, litter decomposition, and crop growth. They showed that seed dressing significantly reduced the surface activity of earthworms with no difference between the use of insecticides or fungicides. Moreover, the effects of seed dressing on earthworm activity were intensified by herbicides (significant herbicide $\times$ seed dressing interaction). They concluded that the interactive effects on soil biota and processes of different pesticide classes should receive more attention in ecotoxicological research.

Integrating process-based knowledge in risk assessment

Pesticide fate models

Numerous models have been developed to simulate the fate of pesticides in the environment following their application to agricultural fields, both at the field and catchment scales (Mottes et al., 2014). The pesticide fate models are considered extensive, economic and efficient tools to predict the fate of pesticides in addition to field and laboratory data. They take into account most of the major processes involved in the fate of pesticides in the environment such as sorption, degradation, leaching, volatilization, plant uptake and wash-off, erosion and runoff, but the processes considered depend on the model (Table 1). The model structure will therefore influence how pesticides are subjected to dissipation transfer processes and how they are distributed into different environmental compartments or into different spatial units.

Among the various existing models, some of the most used are 1D field-scale models that are used for risk assessment of groundwater contamination for pesticides registration at the European level (FOCUS, 2000): MACRO (Model of Water Flow and Solute Transport in Macroporous Soil), PEARL (Pesticide Emission model At the Regional and Local scales), PELMO (Pesticide Leaching Model), and PRZM (Pesticide Root Zone Model). These models differ in their description and consideration of the various processes. For example, in PRZM and PELMO, the soil hydrology is based on a 'tipping-bucket' approach where water will only percolate to the deeper soil layer if field capacity is exceeded, while MACRO and PEARL implement the Richards equation to simulate the water flow. Solute transport used to be described by the advection-dispersion equation.

The soil is generally considered as homogeneous with one porosity form, except in MACRO which describes preferential flow processes by dividing the soil pore system into two flow domains, micropores and macropores. Sorption is considered an instantaneous process and is simulated through linear, and Freundlich formalisms. First-order degradation kinetics of pesticides is assumed by the four models, although PRZM also enables the use of a bi-phasic equation for this process. MACRO simulates

Table 1 Summary of the most important processes simulated by PELMO, PRZM, PEARL, MACRO (FOCUS, 2000) and HYDRUS (Šimůnek et al., 2008) models at the local (soil profile or plot) scale.

degradation and sorption processes in both micro- and macro-pore domains. All four models can take into account the effect of soil moisture content and soil temperature on the rate of pesticide degradation. PEARL, PELMO and PRZM can simulate the pesticide volatilization, while MACRO does not include a comprehensive description of this process. PRZM and PELMO simulate soil erosion and surface runoff in contrast to MACRO and PEARL. The efficiency of these models was tested for different pesticides under several crop and pesticide conditions; for example, MACRO was the most efficient model to simulate the leaching of pesticides to groundwater and their dissipation in a maize (*Zea mays* L.) crop (Marín-Benito et al., 2014).

The 2D and 3D models, such as HYDRUS-2D and HYDRUS-3D (Šimůnek et al., 2008) can simulate water, heat, and solute movement in two- and three-dimensional variably saturated media. In HYDRUS, water flow is solved by the Richards equation while solute transport is modeled with the advection-dispersion equation assuming first-order degradation kinetics of the solute in the liquid and solid phases, and an instantaneous and linear sorption of the solute onto soil solid surfaces. Degradation depends on temperature and water content. The soil hydraulic functions (water content and hydraulic conductivity) are described with the van Genuchten-Mualem model (Šimůnek et al., 2008). HYDRUS-2D can simulate the fate of some pesticides and also the soil water content and fluxes at the plot scale over a pluriannual crop rotation (wheat, maize) accounting for the effects of lateral heterogeneities created by soil tillage and the incorporation of organic amendments (Filipović et al., 2016).

Overall, existing models could be improved by considering, among others, (1) more detailed description of agricultural practices; (2) particulate transfer; (3) refined climatic time scale. Accounting for spatial and temporal scales in pesticide fate modeling remains an important challenge for research. From the point of view of users, i.e. for water resources management, models can be potential tools for three types of action: (1) diagnostic tool to assess the risk of contamination and (2) to identify vulnerable areas for priority protection and or (3) decision tool for choosing adapted measures to limit pesticide transfer at the catchment or regional scale. For example, many studies have been concerned with either vulnerability diagnostics or measures to protect and restore catchments used for drinking water. Nevertheless, there is a critical need for methodological research to evaluate action programs based on the use of spatialized models able to simulate the fate and transfer of pesticides over pluriannual periods. Moreover, such tools have to be able to describe horizontal transfers between plots or landscape elements, which requires the development of territory-scale models that take into account the effect of landscape elements on these transfers, whether hydrological or atmospheric. This remains one of the major challenges of current developments. Treating the question of uncertainties is another important challenge considering both variation in the soil, climate, plants, agricultural practices and other related properties, and the simplification inherent in modeling and the coupling between models which is necessary for integrating spatial and time-dependent processes.

Concluding remarks and the future

There is considerable literature on pesticides, on the processes involved in their fate in soils and on their environmental impacts, mainly concerning ecotoxicological effects and water contamination. The impacts on air and soil contamination have been less well studied. Part of this knowledge has been used to design numerical models describing the fate of pesticides and for risk assessments in the context of registration procedures. The available information on pesticide fate in soils is limited at certain levels of detail because of the large number of different pesticide molecules, and agronomic and environmental situations. It is often difficult to go beyond case studies for a given pesticide and a given situation and to obtain a generic understanding for different situations.

Knowledge gaps and data deficiencies remain, for example, in the consideration of real situations that involve not only active substances, but also formulated commercial products. Standard methods for characterizing adsorption and degradation take little account of the heterogeneity of soils, and also fluctuations in experimental conditions (temperature, water content). Spatial micro-heterogeneities linked to soil structure will condition the accessibility of pesticides to adsorption sites, but also to the microorganisms responsible for their degradation. The behavior of pesticides under extreme conditions, e.g., at very low water contents on the surface of dry soils, are considered very little in the literature, although they may have an important effect on the processes of adsorption, degradation and volatilization.

Finally, the soil processes involved in the fate of pesticides have their own kinetics. Standard methods of characterization tend to focus on short-term or fast processes, which do not describe slow processes adequately, e.g., long-term adsorption, formation of non-extractable residues, or ecotoxicological impacts on biodiversity.

Abstract

Molecular modeling (MM) methods achieved an enormous success in fields such as chemistry or pharmacy. The first attempts to use MM methods in soil science are about 25 years old; however, their wider applicability in soil research is still limited mainly due to extreme soil complexity and diversity. This chapter introduces the most important methodological approaches of quantum mechanics and force field methods and provides several examples evidencing the usefulness and applicability of the MM methods in the soil science. The examples comprise modeling of soil organic matter, the simulation of organo-mineral interactions and adsorption of organic pollutants to soil components.

Glossary

Ab initio modeling Computational chemistry methods based on quantum chemistry, aiming at the approximate solution of the Schrödinger equation.

Force-field methods A group of methods aiming at calculating forces between atoms in a molecule or between molecules. The required parameters can be derived from physical or chemical measurements or from quantum chemical calculations.

Key points

- Discuss why detailed modeling on the molecular level is useful in soil science.
- To show which methods of molecular modeling (MM) can be applied in soil research.
- Potentials and limitations of MM.
- Modeling of the highly complex soil organic matter (SOM).
- Examples on using MM in modeling of interactions of SOM with reactive mineral surfaces and adsorption of organic species in soil.

Introduction

Soil is a highly complex system. Mineral and organic soil components form a unit with soil organisms, plant roots, soil water and soil air. The physical, chemical, and biological processes taking place in the soil are strongly modified by environmental conditions and are thus dynamic, i.e., subject to continuous change. Viewing the soil as a black box permits the derivation of statistical models about the relationships between soil conditions, but it is not possible to understand the fundamental processes. Many of these

processes, such as the binding of pollutants and nutrients in the soil, the stabilization of soil organic matter (SOM), the wettability of soil with water, or also changes in the chemistry due to the activity of soil organisms and plant root secretions, take place on the molecular scale. Analytical methods have made enormous progress in soil research over the past decades. Today, many of the latest physical, chemical and biological investigation methods can be used. They have been adapted for use in soil research and can describe reactions and processes in great detail. For example, X-ray photoelectron spectroscopy (XPS) methods can now be used to investigate elements found in soil surfaces (layer thickness of approx. 10 nm) on a microscopic scale. Atomic Force Microscopy can elucidate adsorption processes by measuring the interaction energy under some conditions. However, even today's cutting-edge analytical methods only provide limited information about probable conformations of organic molecules and their stability in the soil. Also, the detailed interaction mechanisms of inorganic or organic substances with reactive soil surfaces and especially their stability are still not fully accessible to highly specialized analytics—and therefore, not entirely understood. This is where molecular modeling (MM) and simulation can come in. The MM methods, due to the enormous developments in the power of computers, are now able to describe in detail systems that range from the very small atomic scale, by producing approximate solutions to the Schrödinger equation (SE), to larger ones with a few thousand atoms, with methods that require much less computer resource in relation to the size of the systems. The great challenge here is to bridge the spatial and temporal scale boundaries, and to use the results of molecular modeling to explain phenomena observed microscopically and macroscopically in soil.

The use of MM methods in soil research is now much wider than 20 years ago. Since then, many successful results have been achieved, as had been predicted by Gerzabek et al. (2001). By providing a detailed molecular insight, MM has contributed to the understanding of soil experimental measurements correlating the structure, physicochemical properties, and functions of the soil and of soil components (Schaumann, 2006). The importance of MM lies in the processing of interactions between soil components, their environment, and other substances present (Devarajan et al., 2020). As an example, modeling of SOM in the presence of soil minerals has contributed to elucidate the stabilization and protection mechanisms of organic matter (Loganathan et al., 2020; Zhang et al., 2020). Likewise, modeling of SOM with different metal ions has led to the understanding of processes that control speciation, solubility and toxicity at the molecular scale (Liang et al., 2019). A particular subject of interest was prediction of the bioavailability of pollutants in soil such as agrochemicals (Haberhauer et al., 2001), drugs (Aristilde and Sposito, 2010) and waste products (Lan et al., 2019).

In this chapter, we show how MM methods can be used and of what they are capable, based on the methodological background and individual case studies. Soil organic matter is well studied in terms of its elemental composition, functional groups, chemical and physical properties, as well as its functions and processes. However, there are still large gaps regarding the structure and conformation of SOM, which is a mixture of an incredibly large number of molecules that are probably different from each other. This is where MM can make a difference. In particular, based on the existing state of knowledge, computer methods can be used to calculate models of molecules that correspond to the observations in terms of their properties. Particularly important questions that MM can help to solve are, for example, (i) the stability of organic matter and the formation of supramolecular structures, (ii) the interaction of organic molecules and associations with reactive mineral surfaces, such as clay minerals and pedogenic oxides, and (iii) the interaction of organic contaminants with mineral surfaces and soil organic matter.

Computer simulation of reality

Long before the advent of computers, scientists have been making models of reality. In this context, the word model may refer to physical models of objects that are either too small or too large to study in reality. One can think of a physical molecular model, like the structures of DNA that were built by Watson and Crick, or a planetarium describing the motions of the planet. A model can also take the form of a philosophical model, that describes the current thinking about complex processes or the composition of complex mixtures, like soil. Our view of the real world is quite limited but becomes accessible through models. Fig. 1 shows schematically how experiments may be performed in the real world, leading to experimental data (van Gunsteren et al., 2006). These data enable

Fig. 1 Computational soil science involves the formulation and testing of mathematical models of the real world. Adapted from van Gunsteren WF, Bakowies D, Baron R, Chandrasekhar I, Christen M, Daura X, Gee P, Geerke DP, Glättli A, Hünenberger PH, Kastenholz MA, Oostenbrink C, Schenk M, Trzesniak D, Van der Vegt NFA and Yu HB (2006) Biomolecular modeling: Goals, problems, perspectives. *Angewandte Chemie International Edition* 45: 4064–4092. (At: <https://onlinelibrary.wiley.com/doi/10.1002/anie.200502655>).

classifications and abstractions, which together with simplifications, approximations and generalizations lead to a model of the real world. If such models can be digitized, we obtain a computer model. Mathematical methods can subsequently be applied to obtain predictions, which can once more be compared to (independent) experimental data to validate or falsify the model.

The main reason to create molecular models of soil components is because molecules are the smallest entities that are, in the end, responsible for the behavior of virtually all physical processes. A true understanding of properties and processes of soil will only be possible at the molecular level. However, the experimental data that are obtained in the real world, contain very little information about the behavior of individual molecules. Rather, these data are representative of averages over many complex molecules and over time scales that are long compared to typical molecular motion. To obtain a visualization and an in-depth understanding of the relevant processes, one can turn to molecular models. It is important to note, therefore, that computational modeling and real-world experiments are complimentary in their description of the real world. Macroscopic properties may be described phenomenologically, with the physical basis being understood from much simplified models. One of the main challenges is to bridge the space and time-scale gap between the experiments in the real world and the models. In other words, to ensure that the simplifications and approximations made in the model building are appropriate for the aspects of physical processes that one aims to understand.

Molecular modeling methods

This section briefly summarizes molecular modeling methods of computational chemistry that are applicable in soil sciences. Details can be found in many excellent text books and reviews available in the literature (Cramer, 2004; Frenkel and Smit, 2002; Leach, 2001; Young, 2001).

Depending on the approximations and simplifications one is willing to make, various models at different levels of resolution can be constructed. Such models will differ in the elementary particles that are being treated. Three relevant examples for molecular models of a single molecule are given in Fig. 2.

Generally, molecular modeling comprises two basic groups of methods built on principles of (a) quantum chemistry (QC) and (b) force field (FF) methods, respectively. The QC methods describe systems as a set of mutually interacting nuclei and electrons, and complete information about the system can be achieved by an approximate solution of the SE. In the FF methods, classical particles represent a model system consisting of interacting particles (e.g., atoms, or larger beads representing a functional group or set of atoms) and the main task is to find proper, relatively simple analytical expressions able to describe a potential energy hypersurface of the system under study. The smallest degree of freedom that is taken into account in FF is no longer an electron, but we describe the system in terms of entire atoms that are connected to each other in some way. This means that we are no longer able to break chemical bonds. In a way, we are trying to capture the average effect of the electrons in the force field equations to come to a coarser description of the model. We can continue to make our description coarser and try to average over additional degrees of freedom (see Fig. 2). We would need to capture the mean effect of the neglected degrees of freedom within specific FF contributions. Examples of this are FFs that describe the presence of a solvent in an implicit way, or FFs in which the elementary particles are beads that are representative of multiple atoms, e.g., an entire functional group, or a set of 4–5 water molecules. The advantage could be that fewer degrees of freedom are explicitly calculated, reducing the computational effort at the cost of a loss of detail in the

Fig. 2 Three representations of the same organic molecule.

description. Such FFs typically use very similar functions to those that will be described below, but will not be discussed explicitly. Nevertheless, the decision as to what level of description will be most appropriate is a crucial one in any modeling effort, posing such questions as follow. Are the electronic degrees of freedom necessary, or is an atomistic description of the system sufficient? Can the degrees of freedom be reduced even further, or would we lose relevant details if we make our description even coarser? The sections below discuss QC and atomistic FF methods in more detail.

Quantum chemistry

Fig. 3 shows a basic classification of QC methods. The core of quantum chemistry is the SE that fully describes the space- and time-evolution of a system consisting of interacting electrons and nuclei. Mathematically, the SE is a second-order partial differential equation. Its non-relativistic time-independent form is

$$\hat{H}\Psi = E\Psi \quad (1)$$

where $\hat{H}$ is the differential Hamiltonian operator, E is the total energy, and Ψ is the many-body wave function of the system. The Hamiltonian operator is the sum of the kinetic and potential energy operators

$$\hat{H} = -\sum_i \frac{1}{2m_i} \nabla^2 + V(\mathbf{R}, \mathbf{r}) \quad (2)$$

where m_i is the mass of the i th particle (electron or nucleus), ∇^2 is the Laplacian operator and $V(\mathbf{R}, \mathbf{r})$ is the operator describing the potential energy representing the Coulombic interactions of all n_e electrons and all n_N nuclei. $\mathbf{R}$ and $\mathbf{r}$ are position vectors of nuclei and electrons, respectively. Thus, the total energy E in Eq. 1 is the sum of the kinetic energy of all electrons and nuclei, and interaction energies between all electrons ($e-e$), nuclei ($N-N$), and electron and nuclei ($e-N$) (Eq. 3).

$$E = T_e + T_N + V_{ee} + V_{eN} + V_{NN} \quad (3)$$

The existence of a wave function Ψ is one of the postulates in quantum chemistry. The square of the wave function is interpreted as the probability of finding an electron in a configurational space. Generally, an exact solution of the SE for a many-body system is not possible and practical solutions require approximations. The most common is the *Born–Oppenheimer (BO) approximation* that assumes the SE solution separately for nuclei and electrons because electronic motion is much faster than nuclear motion (nuclei are much heavier than the electrons by a factor ~ 1830). Thus, the electronic wave function only depends parametrically on the positions of the nuclei ($\hat{H}(\mathbf{r}, \mathbf{R}) \rightarrow \hat{H}_{BO}(\mathbf{r} | \mathbf{R})$; $T_N = 0$ and V_{NN} is a parameter in Eq. 3). The next two approximations leading to the practical solution are (a) application of the *variational principle* and (b) expression of the many-electron wave function as a product of one-electron wave functions (*Hartree–Fock* method, HF). The variational principle supposes we select a trial wave function that depends on one or more parameters, $\mathbf{p}$, $\Psi(\mathbf{r} | \mathbf{R}, \mathbf{p})$. By varying these parameters, it is possible to find a minimum for $E[\Psi]$ (eigenvalue). In other words, to fulfill the condition for the stationary point, the following should be true.

$$\frac{\partial E[\Psi]}{\partial p_i} = 0 \quad (\text{for all } i) \quad (4)$$

If Ψ is exact, then the solution is the exact energy for any other Ψ , $E[\Psi] \geq E_{\text{exact}}$.

Fig. 3 Schematic categorization of the quantum chemical methods.

Wave function methods

The concept of the HF method is based on a specific approach of “independent particle model” meaning that the trial wave function is expressed as a product of one-electron wave functions, ψ_i , (called molecular orbitals).

$$\Psi_{\text{HF}} = |\psi_1 \psi_2 \cdots \psi_i \cdots \psi_n| \quad (5)$$

The Ψ_{HF} should fulfill the Pauli exclusion principle (sign is changed if two electrons are permuted). The HF solution means that each individual electron moves in an averaged field of all the remaining electrons and a mutual correlation of electron movement is neglected (mean field model).

For a practical solution, the orbital wave functions are expressed in a set of auxiliary functions (called atomic orbitals—basis set) as

$$\psi_i(\mathbf{r}) = \sum_{\mu} c_{\mu i} \phi_{\mu}(\mathbf{r}) \quad (6)$$

where a molecular orbital ψ_i is represented as the sum of n atomic orbitals ϕ_{μ} (μ runs from 1 to n) and $c_{\mu i}$ are unknown linear expansion coefficients. ϕ_{μ} represents the basis set of the i th molecular orbital. The variation of wave function with respect to these coefficients leads to the set of Hartree-Fock Roothaan nonlinear equations

$$F\psi_i = \varepsilon_i \psi_i \quad (7)$$

where F is a Fock operator (FO) and ε_i is the expectation value over the Fock operator representing the average energy of electrons in the i th orbital and the total energy of the system is the sum of all orbital energies $E_{\text{tot}} = \sum \varepsilon_i$.

The FO depends on its own eigenfunctions; thus, the solution of Eq. (7) requires an iterative approach—(a) estimate initial orbital coefficients → (b) calculate FO → (c) diagonalize FO to obtain new orbitals → (d) calculate E_{tot} → (e) check energy convergence—if E_{tot} is converged, stop, else go back to step (b).

Although the HF solution is approximative, it covers >99% of the exact energy. Unfortunately, the missing part (correlation energy, CE) can lead to large errors because in chemistry we require accuracy of $\sim 1 \text{ kcal mol}^{-1}$. Therefore, to improve accuracy of the HF solution required the development of methods able to include correlation energy in the calculation. These methods (post-HF methods) are categorized into several groups such as (i) Configuration Interaction (CI) methods, (ii) Møller–Plesset perturbation theory (MPx) methods, and (iii) Coupled Cluster (CC) theory methods. The form of CC, which includes singles and doubles and non-iterative triples (CCSD(T)), is considered a very accurate method frequently called the “gold standard” in quantum chemistry.

A decision to select a particular ab initio method is affected mainly by the size of the system (number of electrons, n), property(ies) to be calculated, computational time required and available computational resources. The wave function-based methods discussed above are computationally scaling with n^4 and more; thus, the size of the system is an important factor. A special category of the QC methods is represented by semiempirical and density functional tight binding (DFTB) methods suitable for systems of thousands of atoms. In semiempirical methods some complicated integrals are replaced by empirical parameters reducing the computational time substantially with scaling n^{2-3} ; however, the price for that in many cases is a decrease in accuracy.

Density functional theory—Basic principles

This section briefly describes principles of the second principal group of quantum chemistry based on the density functional theory (DFT). The DFT-based methods are very popular due to their economy and efficiency compared to the post-HF methods because they scale with $\sim n^3$. Thus, these methods are applicable for large molecular systems consisting of hundreds of atoms. Apart from HF and post-HF methods, energy of the system, $E(\rho)$, is expressed as a function of the three-dimensional electronic density of the system, ρ . The method, appeared in the 1960s and is based on two Hohenberg–Kohn theorems and the practical Kohn–Sham approach.

The first theorem supposes that the electron density completely determines the Hamiltonian operator and, consequently, all the properties (including energy) of the system. The total energy functional in the Hohenberg–Kohn–Sham (HKS) approach can be expressed as

$$E[\rho] = T[\rho] + E_{\text{ee}}[\rho] + \int \hat{V}_{\text{ext}} \rho(\mathbf{r}) d\mathbf{r} = F[\rho] + \int \hat{V}_{\text{ext}} \rho(\mathbf{r}) d\mathbf{r} \quad (8)$$

where $T[\rho]$ and $E_{\text{ee}}[\rho]$ are unknown functionals of the kinetic energy and electron–electron interaction, and $F[\rho]$ is the universal DFT functional. The last term in Eq. (8) represents the electron interactions with the effective external potential.

The second theorem claims that the energy density functional is variational meaning that it has a minimum with respect to variations in the electron density, $\delta\rho(\mathbf{r})$.

These two theorems mean that there is a universal energy density functional $E[\rho]$, which, if it is known, can be varied with respect to the electron density to compute the exact ground state density and energy.

For a practical solution, the universal functional was reformulated as

$$F[\rho] = T[\rho] + J[\rho] + E_{\text{XC}}[\rho] \quad (9)$$

where $J[\rho]$ is a Hartree (classical electrostatic repulsion term) and $E_{xc}[\rho]$ is the exchange-correlation energy containing everything that is unknown. The success of the DFT solution lies in finding proper expressions for kinetic energy and exchange-correlation energy terms.

For example, for a fictitious system of non-interacting electrons the kinetic energy functional can be expressed as a single determinant of n one-electron wave functions (Kohn–Sham orbitals), ϕ_i :

$$T_s[\rho] = -\frac{1}{2} \sum_i^n \langle \phi_i | \nabla^2 | \phi_i \rangle \quad (10)$$

Using this approximation, the electron density can be expressed as

$$\rho(\mathbf{r}) = \sum_i^n |\phi_i(\mathbf{r})|^2 \quad (11)$$

Similarly, as in the HF approach, such HKS reformulation leads to non-linear equations describing non-interacting particles in an effective local potential

$$\left(-\frac{1}{2} \nabla^2 + V_s(\mathbf{r}_i) \right) \phi_i = \varepsilon_i \phi_i \quad (12)$$

where ε_i are energies of corresponding KS orbitals ϕ_i . The practical solution is done in an iterative manner, similar to the HF solution.

The major problem in DFT theory is with the expression of functionals for exchange and correlation energies. This led to the development of numerous solutions starting with the simplest local density approximation (LDA), through the generalized gradient approximation (GGA) method that includes gradients of the electron density to the functional forms, to the hybrid and meta-GGA approaches. From numerous functionals of the GGA theory, we can mention popular functionals such as PBE (Perdew–Burke–Ernzerhof), PW91 (Perdew–Wang 1991), or BLYP (Becke–Lee–Yang–Parr). Details on DFT functionals can be found in many textbooks. From the hybrid functionals, the most popular in the chemical community is the B3LYP that mixes the HF exact exchange with the DFT exchange–correlation using adjustable parameters. Its popularity arises from provision of relatively good accuracy in predicted properties of many chemical systems. From the beginning of DFT theory it was found that DFT functionals can frequently fail in a prediction of properties such as charge–transfer, excited states, or weak dispersion interactions. The main reason is the inability to account for a nonlocal electron correlation effect. Thus, there is a systematic development of DFT functionals dealing with this problem. This effort brings new methods at several levels of theory—from purely empirical corrections to the standard DFT functionals to rigorous dispersion functionals derived from first principles. Thus, the main message for the practical application of DFT methods is in the understanding of basic principles, limiting accuracy of the particular DFT functionals and their applicability and suitability with respect to the chemical nature of the modeled system.

Force field methods

We mentioned above the Born–Oppenheimer approximation, which states that from the electron’s point of view, the nuclei seem to be standing still and the electron cloud around them will be adjusted instantaneously. The positions of the nuclei are therefore parameters of the Hamilton operator, and the resulting electronic energy is a function of the nucleic coordinates. Given a certain configuration of the nuclei (their positions), the electrons will adjust instantaneously and this leads to a certain energy. This gives us a direct link between the nucleic coordinates and the energy of the system. If the nuclei are positioned in an unfavorable configuration, the electrons cannot adjust around them and this will lead to relatively high energy, while a molecule that is in a favorable configuration, will lead to a lower energy. From the point of view of the nuclei, the Born–Oppenheimer approximation implies that they move according to a potential energy that is given by the electrons and is a function of the atomic coordinates.

Calculation of the electronic wavefunctions and associated energies may be computationally quite demanding, but they are crucial in cases where the electronic degrees of freedom are important. For instance, if one is interested in chemical reactions in excited electronic states (e.g., to study fluorescence) or in electron transfer reactions, the electrons should be taken explicitly into account. However, in many systems, we are interested in how the molecules behave, but not particularly in the electronic degrees of freedom. We can then try to approximate the potential energy of the molecular system with a simplified equation that captures the mean effect of the electronic degrees of freedom. Such an approximation is what we call a force field (FF), and it typically involves various energy terms that describe certain aspects of the potential energy the nuclei experience. The calculation of FF energy is usually orders of magnitude faster than solving the SE (Eq. 1), therefore it can be done for a significantly larger number of particles.

A force field defines the total potential energy, $V^{\text{pot}}(\mathbf{r})$, as a function of the atomic coordinates, $\mathbf{r}$. The position of a single particle i is denoted with the three-dimensional vector $\mathbf{r}_i$. $V^{\text{pot}}(\mathbf{r})$ can be written as the sum of various contributions, for example

$$V^{\text{pot}}(\mathbf{r}) = V^{\text{bonded}}(\mathbf{r}) + V^{\text{nonbonded}}(\mathbf{r}) \quad (13)$$

It is common to distinguish the bonded interactions, $V^{\text{bonded}}(\mathbf{r})$, and the nonbonded interactions, $V^{\text{nonbonded}}(\mathbf{r})$. As the name implies, the bonded interactions come from the interactions of atoms that are bound to each other in some way, while the

nonbonded interactions represent the interactions between atoms through space, rather than through some set of chemical bonds. The bonded and nonbonded energy terms are themselves again the sum of various more specific terms that will be outlined below. Additional FF terms may be added to model specific aspects. The definition of a specific force field consists of everything we need to approximate the molecular potential energy. This means that a force field consists of a detailed description of the functional form that is used, together with all the parameters that are needed to compute the energy from the atomic coordinates.

The bonded interactions are typically split further into contributions related to bond stretching, bond-angle bending, torsional dihedral angle rotations and out-of-plane or improper dihedral angle terms,

$$V^{\text{bonded}}(\mathbf{r}) = V^{\text{bond}}(\mathbf{r}) + V^{\text{angle}}(\mathbf{r}) + V^{\text{torsion}}(\mathbf{r}) + V^{\text{improper}}(\mathbf{r}) \quad (14)$$

Most force fields, approximate the potential energy associated with a single bond by a harmonic potential, as in

$$V_i^{\text{bond}}(\mathbf{r}) = \frac{1}{2} K_i^b [b_i(\mathbf{r}) - b_i^0]^2 \quad (15)$$

where K_i^b is the harmonic force constant and b_i^0 is the optimal bond length. These are the parameters of this force field term, and $b_i(\mathbf{r})$ is the actual bond length that can be computed from the atomic coordinates. Bonds are stiff degrees of freedom, allowing for little fluctuation. Assuming an average energy of RT (accounting $\sim 2.5 \text{ kJ mol}^{-1}$ at room temperature, R is an ideal gas constant of $8.31446261815324 \text{ J K mol}^{-1}$), and a force constant of $0.33 \times 10^6 \text{ kJ mol}^{-1} \text{ nm}^{-2}$, for example, an aliphatic carbon-carbon bond, the harmonic function in Eq. (15) can fluctuate by approximately 0.004 nm:

$$2.5 = \frac{1}{2} \times 0.33 \times 10^6 [b_i(\mathbf{r}) - b_i^0]^2 \Rightarrow [b_i(\mathbf{r}) - b_i^0] \approx 0.004 \text{ nm} \quad (16)$$

So, the typical fluctuations that can be expected are in the thousandths of a nanometer. The associated period of a single fluctuation is on the order of 10 fs.

For the potential energy of an individual bond angle, most force fields use, again, a harmonic potential

$$V_i^{\text{angle}}(\mathbf{r}) = \frac{1}{2} K_i^\theta [\theta_i(\mathbf{r}) - \theta_i^0]^2 \quad (17)$$

where K_i^θ is the harmonic angle-bending force constant, θ_i^0 is the minimum energy angle value and $\theta_i(\mathbf{r})$ is the actual angle, which can be computed from the molecular configuration. At room temperature, for typical angles in organic molecules, one expects fluctuations of $5\text{--}10^\circ$.

Four atoms that are sequentially connected by three bonds, $i\text{--}j\text{--}k\text{--}l$, will give rise to a torsional profile, corresponding to a rotation around the $j\text{--}k$ bond. The potential energy as a function of the torsional angle ϕ , will be a periodic function, so a functional form that is based on a cosine seems to be a sensible choice. One common form would be

$$V_i^{\text{torsion}}(\mathbf{r}) = K_i^\phi [1 + \cos(m_i \phi_i(\mathbf{r}) + \delta_i)] \quad (18)$$

where K_i^ϕ is the force constant, or half barrier height, m_i is the multiplicity of the torsional term, which determines the number of maxima and minima that is observed along a full turn, δ_i is a phase shift, with which we can determine, if a zero-degree angle should be a maximum or rather a minimum of the potential energy and $\phi_i(\mathbf{r})$ is the actual value of the dihedral angle, which can be computed from the atomic coordinates. It can be defined as the angle between the plain through atoms i , j and k and the plain through atoms j , k and l .

To ensure a proper coordination of four atoms that should remain in a plain or in a tetrahedral arrangement an out-of-plane or improper dihedral angle term may be included. The coordinate ξ is used to define the spatial arrangement, which can then be enforced using a harmonic potential energy term:

$$V_i^{\text{improper}}(\mathbf{r}) = \frac{1}{2} K_i^\xi [\xi_i(\mathbf{r}) - \xi_i^0]^2 \quad (19)$$

The nonbonded interactions in Eq. (13), theoretically run over all pairs of atoms and consist of nonpolar interactions, $V^{\text{nonpolar}}(\mathbf{r})$, and the electrostatic interactions, $V^{\text{elec}}(\mathbf{r})$, such that we can write

$$V^{\text{nonbonded}}(\mathbf{r}) = \sum_{i=1}^N \sum_{j>i}^N [V_{ij}^{\text{nonpolar}}(\mathbf{r}) + V_{ij}^{\text{elec}}(\mathbf{r})] \quad (20)$$

with the nonpolar (dispersion) interactions typically approximated by the Lennard-Jones potential:

$$V_{ij}^{\text{nonpolar}}(\mathbf{r}) = V_{ij}^{\text{LJ}}(\mathbf{r}) = 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] \quad (21)$$

where ϵ_{ij} is the well-depth of the interaction at the minimum energy distance, and σ_{ij} is the distance at which the potential energy passes through zero, i.e., switches from attractive to repulsive, and r_{ij} is the distance between particles i and j .

The electrostatic interactions are given by Coulomb's law

$$V_{ij}^{\text{elec}}(\mathbf{r}) = \frac{1}{4\pi\epsilon_0\epsilon} \frac{q_i q_j}{r_{ij}} \quad (22)$$

where ϵ_0 is the dielectric constant of a vacuum and ϵ is the relative dielectric constant of the medium, q_i and q_j are the partial charges of particles i and j . The electrostatic interaction energy decays as $1/r_{ij}$, which means that this interaction acts at a considerably longer range than the nonpolar interactions. Usually, the nonpolar interactions beyond a distance of, for example, 1.4 nm are typically ignored, while for the electrostatic interactions this would be too rough an approximation. Long range effects can be included either in a mean-field way, using a reaction-field contribution,

$$\Phi_i(r_i) = \frac{1}{4\pi\epsilon_0\epsilon} \sum_{j=1}^N q_j \left[\frac{1}{r_{ij}} - \frac{C_{\text{rf}} r_{ij}^2}{2R_{\text{rf}}^3} - \frac{1 - \frac{1}{2} C_{\text{rf}}}{R_{\text{rf}}} \right] \quad (23)$$

where R_{rf} is the reaction-field cut-off that we apply and C_{rf} depends on the relative dielectric constant, ϵ_{rf} , and the inverse Debye screening length, κ_{rf} , of the medium outside the cutoff,

$$C_{\text{rf}} = \frac{(2\epsilon - 2\epsilon_{\text{rf}})(1 + \kappa_{\text{rf}} R_{\text{rf}}) - \epsilon_{\text{rf}}(\kappa_{\text{rf}} R_{\text{rf}})^2}{(\epsilon + 2\epsilon_{\text{rf}})(1 + \kappa_{\text{rf}} R_{\text{rf}}) + \epsilon_{\text{rf}}(\kappa_{\text{rf}} R_{\text{rf}})^2} \quad (24)$$

Alternatively, the long-range interactions can be taken into account explicitly for condensed phase systems, by applying periodic boundary conditions. The electrostatic potential on an infinite, periodic lattice can then be approximated by lattice-sum methods such as Ewald summation or its variants like particle-mesh Ewald (PME) or particle-particle-particle-mesh (P3M) methods. However, these approaches may introduce an artificial periodicity that could affect the outcome of the calculations.

Force field parameterization

For all of the potential energy terms described in the previous section, there are FF parameters involved. These parameters may be specific for a given molecule, in a given environment and under given thermodynamic boundary conditions. Because it is not feasible to determine all FF parameters for a given system and conditions, we tend to rely on the transferability of many of the FF parameters. It is likely that a carbon-carbon bond in a butane molecule does not vibrate very differently from a carbon-carbon bond in pentane. The aim is to obtain a set of parameters that can be used for as large a set of molecular systems as possible. For this reason, FF parameters are typically derived from smaller molecules, to then apply in larger molecular systems. To facilitate the choice of parameters, this set should be kept as small as possible and also to avoid the risk of overfitting, since there may not be sufficient data to parameterize, for example, the nonpolar parameters for all possible pairs of atom types in different chemical environments.

Furthermore, the choice of parameters for one potential energy term, may strongly influence the choice of parameters for another potential energy term. For example, the nonpolar interactions and the electrostatic interactions are tightly coupled. They both derive from a model in which the electron cloud around some nuclei governs the nonbonded interactions, and it is to some extent a matter of choice how much of the nonbonded interaction energy is represented by the nonpolar and how much by the electrostatic interactions. This strong interdependence of the FF parameters poses a considerable challenge to the parameterization of a force field: all parameters need to be determined self-consistently and preferably lead to the description of transferable functional groups.

There are many different types of force fields described in the literature. For biomolecular systems, there is a choice of AMBER, CHARMM, GROMOS, OPLS, etc. and each of these come in different parameter sets or releases (Riniker, 2018). For mineral systems (specifically aluminosilicates), the ClayFF has been derived (Cygan et al., 2004). When one needs to model molecules that have never been described in the force field of choice yet, it is tempting to “borrow” the parameters from another force field. The strong interdependency of the parameters will usually lead to there being a poor mix of parameters that do not work together. It could result in distorted molecules, or in the absence of properties that should emerge from the interactions, like hydrogen bonds.

As a final remark, the simulation settings that were used in the parameterization of the force field (e.g., electrostatic parameters, cutoffs) should be considered an integral part of the force field and may further limit the transferability of parameters between force fields and parameter sets.

Examples for applications in soil science

Most soils consist of macroaggregates, which in turn are composed of smaller microaggregate structures that comprise mineral, organic and biotic materials linked during pedogenesis. It is known that SOM-SOM, SOM-mineral and mineral-mineral interactions initiate the build-up of composite building units and thus the processes of microaggregate formation. The vast diversity of components in a given aggregate (Fig. 4, Lehmann et al., 2008) provides an architecture intimately linked to the functions of the soil such as the C-storage or the fate of nutrients and pollutants in the environment.

Humic substances (HSs) can be considered a major component of SOM. Thus, they can play a key role in important soil functions. A variety of models has been proposed aimed to represent HS. These models consider either the existence of hypothetical molecules whose composition resembles the functional groups observed in the organic fraction of the soil matrix, or active sites of interaction, such as hydrophilic groups as part of long hydrocarbon chains. These models have served as the basis to approach possible structural arrangements or describe mechanisms of interactions such as aggregation of SOM. Here, cations, particularly those with high ionic potentials (z/r) such as Mg^{2+} and Ca^{2+} , contribute significantly to aggregation through electrostatic interactions with negatively charged sites represented mainly by carboxylate groups. Similarly, modeling also allowed description of the formation of complexes of SOM and dissolved organic matter (DOM) with neutral xenobiotic compounds (e.g.,

Fig. 4 Distribution of carbon contents in a soil micro assemblage from Nandi Forest (Kenya) determined by NEXAFS (Near-edge X-ray absorption fine structure) in combination with STXM (Scanning transmission X-ray microscopy). The colors represent different functional groups. Modified from Figure 2 of Lehmann J, Solomon D, Kinyangi J, Dathe L, Wirick S and Jacobsen C (2008) Spatial complexity of soil organic matter forms at nanometre scales. *Nature Geoscience* 1: 238–242. (At: <https://www.nature.com/articles/ngeo155>).

pentachlorophenol, atrazine and dichlorodiphenyltrichloroethane (DDT)) having an origin in dispersive forces and hydrogen bonds (h-bonds) detected then as main factors for their temporary retention in soil.

Soil minerals determine transport, diffusion, runoff, leaching or volatilization process in the environment. On the other hand, soil minerals are also important in material science with cosmetic and pharmaceutical applications. Currently, there are models capable of describing the hydrated crystalline structure of soil minerals and their interface with aqueous solutions and biomolecular compounds. For example, many efforts have been made to characterize clay mineral surfaces with FF-MD, which are now also starting points for modeling organo-mineral complexes that are of utmost importance for the stabilization of SOM in soils.

Modeling of soil organic matter—The Vienna soil organic matter modeler

Humic substances (HSs) stand out as being among the most stable compounds in soil. Their composition and three-dimensional structure are decisive both in sorption processes in the soil matrix and in its functions. The Vienna Soil Organic Matter Modeler (VSOMM) (Sündermann et al., 2015; Escalona et al., 2021) can generate condensed-phase models that are diverse in composition, functional groups and structure according to solid-state and liquid-state ^{13}C nuclear magnetic resonance (NMR) carbon distributions. The Modeler uses the concept of building blocks as the basic units to create HSs samples (Fig. 5), similar to amino acids in biochemistry to assemble more complex structures. Currently, the Modeler utilizes a database of 54 building blocks which can have one or more of the following functional groups: carbonyl-C, carboxyl-C, O-aryl-C, aryl-C, di-O-alkyl-C, O-alkyl-C, methoxyl-C and alkyl-C.

Within the natural organic matter, the intensively studied Leonardite humic acid (LHA) is often used as a model because it is characterized by a high content of HSs, especially humic acids (HAs). The resulting models showed that the hydration level of LHA (Fig. 6, Petrov et al., 2017) affects the mobility of molecules within the soil matrix, as well as the viscosity and density of the samples due to the complex network of h-bonds formed.

The hydrophilic sites of HSs contain carboxylic and phenol functional groups, which give them an acid character, as they can release protons. Because most of this acidity is reactive below pH 7, HSs have a net negative charge in all but the most acidic soils. The electrostatic attraction between the HSs negative charges, HSs and the common soil cations give rise to the formation of cation bridges (Fig. 7, Galicia-Andrés et al., 2021a). These coordination complexes are classified as: inner-sphere complex (ISC) if the ligand (HS) and the metal cation interact directly; or outer-sphere complex (OSC) if they interact through the solvent (e.g., water molecules).

Fig. 5 Assembling process of two building blocks linked together to form HS molecules. (At: <http://pubs.acs.org/doi/10.1021/acs.est.7b00266>).

Fig. 7 Representation of the inner-sphere complex (ISC), bidentate (b), monodentate (m), and outer-sphere complex (OSC) between carboxylate groups and Ca^{2+} cations. HAs as sticks, cations as balls (violet), water molecules as balls and sticks (red and white) and distances are shown in Angstroms. Modified from Figure 5 of Galicia-Andrés E, Escalona Y, Oostenbrink C, Tunega, D and Gerzabek MH (2021a) Soil organic matter stabilization at molecular scale: The role of metal cations and hydrogen bonds. *Geoderma* 401: 115237. (At: <https://www.sciencedirect.com/science/article/pii/S0016706121003177>).

The stability of the coordinated pair depends on the complex formed. The bidentate ISCs are the most stable with two coordinated oxygen atoms, unlike monodentate ISCs in which only one atom is coordinated. Conversely, the OSCs exhibit the least stability by being separated by the solvent and so increasing the probability of dispersing the aggregate. This suggests that the formation of supramolecular aggregates is the result of the interaction between cations and HSs. The aggregation mechanism promoted by the presence of cations is related to the DLVO (Derjaguin–Landau–Verwey–Overbeek) theory formulated for emulsions and colloids.

Interaction of SOM with reactive mineral surfaces

For decades, it was assumed that the stable organic matter consisted mainly of the so-called HSs, the larger complex molecules. It was believed that the microbial degradability of organic substances in the soil varied greatly due to their chemical structures (chemical recalcitrance). At the beginning of this millennium (Schmidt et al., 2011), however, it was increasingly recognized that the rates of degradation of complex molecules, such as lignin, and much smaller molecules, such as sugars or proteins, are very similar. At the same time, interaction with reactive mineral surfaces has been established as a new explanatory model for the stabilization of organic molecules in soil. The decomposition of plant residues to carbon dioxide is thus slowed down by binding of the decomposition products to clay minerals and oxides; stable pools of organic matter are created precisely by this mechanism (Lehmann and Kleber, 2015).

The formation of microaggregates in the soil through physical, chemical, and biological processes takes place in the course of soil development. During the process, additional surfaces are created and aggregation has significant effects on soil functions such as water-holding capacity or the retention of nutrients and pollutants. An essential part of the process is the formation of organo-mineral complexes (Totsche et al., 2018).

These organo-mineral aggregates are stabilized mainly by hydrophobic and h-bond interactions; however, ion-exchange, cation bridges and the dielectric environment also play an important role. Clay mineral surfaces such as the montmorillonite (100) basal surface have a negative charge due to the isomorphous substitutions of cations with lower charges than the primordial cations induced on their basal surface structures. These negatively charged layers promote the adsorption of positively charged species, e.g., counterions, creating a positive surface charge effect. Other positively charged species can compete with counterions on the surface, leading to ion exchange (Grančič and Tunega, 2020). If counterion layers attract negatively charged species, such as HSs, these are adsorbed on the surface via cation bridges (ISCs and OSCs).

On the other hand, surfaces that do not exhibit a net charge, such as the basal surface of kaolinite, the dielectric environment takes precedence. Simulations enable two types of surrounding environments to be modeled with different dielectric properties which influence the SOM adsorption mechanism. Nanopore cavity (periodic) models can polarize the immersed environment (e.g., water molecules) by replicating the model layer an infinite number of times in the direction normal to the exposed surface (Fig. 8A), whereas slab models assume a single layer of infinite surface with the environment non-polarized (Fig. 8B) (Galicía-Andrés et al., 2019).

Both models show SOM adsorbing on the basal surface of kaolinite via h-bonds; however, the polarized environment promotes the breakdown of the supramolecular aggregate and subsequently the dispersion of individual molecules on the surface (Fig. 9). The detached HS molecules are forced to the surface of the alumina octahedral sheet and the cations to the siloxane surface of the kaolinite.

Unlike the aggregate, detached molecules have greater mobility, allowing them to disperse effectively over the surface until its saturation. In contrast, non-polarized models favor the aggregate structures by clustering dispersed molecules through cation bridges. These observations may explain the behavior of SOM as supramolecular aggregates clustered by cation bridges and h-bonds in solution. Once SOM comes into contact with soil minerals, it is adsorbed. When the environment is polarized, as inside a nanopore, the SOM breaks down into its individual components and the molecules are dispersed, trapping SOM inside the nanopore.

Organic contaminant interactions with mineral surfaces and organic matter

Special attention is paid to the fate of pollutants, such as pesticides, antibiotics, and pharmaceuticals, polycyclic aromatic hydrocarbons and oil components, because of their potential effects on the ecosystem (Tunega et al., 2016; Churchman and Velde, 2019). Understanding the mechanisms involved in the sorption processes and the interactions of organic molecules with mineral surfaces and organic matter is a key point in the application of remediation processes.

Glyphosate is one of the most widely used herbicides due to its broad spectrum of selectivity against weeds. However, long-term application may have adverse effects due to the toxicity of breakdown products, leaching to water sources as well as its retention in soil. The main mechanism of interaction between glyphosate and 1:1 clay minerals, such as kaolinite, is through h-bonds, which represent a precursor stage to the formation of complexes. Glyphosate interacts with the surface of the alumina octahedral sheet forming as many h-bonds as possible, i.e., parallel to it (Fig. 10, Galicia-Andrés et al., 2020); although, it is also capable of interacting through its COOH and PO(OH)₂ sites.

Furthermore, the pH solution influences the adsorption strength. In the neutral state glyphosate (pH < 2.3) is weakly adsorbed on the kaolinite ($\Delta G = -5 \text{ kJ mol}^{-1}$) compared to anionic glyphosate ($2.3 < \text{pH} < 6.0$) which exhibits a stronger adsorption ($\Delta G = -14 \text{ kJ mol}^{-1}$) due to its ionic nature. This behavior is strongly enhanced when the glyphosate is inside a nanopore cavity. In contrast, the adsorption strength of the neutral glyphosate is not influenced by the polarized environment, however some degrees of freedom are restricted.

Fig. 10 Representation of neutral glyphosate in solution in contact with a kaolinite Al-octahedron layer. Modified from Figure 1 of Galicia-Andrés E, Tunega D, Gerzabek MH and Oostenbrink C (2020) On glyphosate–kaolinite surface interactions. A molecular dynamic study. *European Journal of Soil Science* 72: 1231–1242. (At: <https://doi.org/10.1111/ejss.12971>).

The model represents a solute-medium completely interacting form ($\lambda = 0$) and a non-interacting ($\lambda = 1$). Modified from Figure 1 of Petrov D, Tunega D, Gerzabek MH and Oostenbrink C (2020) Molecular modelling of sorption processes of a range of diverse small organic molecules in Leonardite humic acid. *European Journal of Soil Science* 71: 831–844. (At: <https://onlinelibrary.wiley.com/doi/10.1111/ejss.12868>).

Similar to soil minerals, SOM can incorporate pollutants into its matrix. This sorption capacity depends on the composition and three-dimensional structure of SOM, as well as environmental variables such as water content, pH solution and cation content (Fig. 11, Petrov et al., 2020). It is known that water associated with SOM enhances or weakens the adsorption potential, however, small compounds can influence SOM–water interactions as well affecting its hydration state. These interactions are mainly controlled by the polar interactions (i.e., electrostatic interactions and h–bonds) and hydrophobic moieties between sorbent and water molecules.

Sorption free energies of sorbate molecules on hydrated LHA exhibited similar values to hydration free energies, attributed to the preferential location of sorbate molecules to water patches. This behavior explains why adsorption of sorbents depends strongly on the location of the soil particle.

Conclusions and outlook

Molecular modeling and simulation have been used frequently in the chemical sciences for several decades. For example, it is hard to imagine current day drug development without it. The enormous advances in computer performance during the past few decades have enabled the simulation of relatively large systems in a comparatively short time. This strong performance of the methods makes it increasingly possible to model very complex systems, such as soil organic matter or the soil matrix in general. Today, soil science benefits in several ways from the methodological developments in modeling. The ab initio methods are able to calculate systems with an increasing number of atoms and thus can obtain results independently of experiments. The FF methods can handle large systems with a multitude of molecules and are an important bridge to the experimental systems. The results of MM can be used to explain and discuss experimental data, as many interactions that are important in soil cannot be reproduced in the necessary detail experimentally. In the present chapter some relatively complex systems up to organo-mineral complexes in soil have been presented as examples. Tools such as the VSOMM now provide completely new views, consistent with known experimental knowledge, of the complex structures and interactions that characterize soil organic matter. The organo-mineral interactions presented here point to the great future potential of MM. Numerous “hot” topics in soil research, such as SOM stabilization, the binding mechanisms of non-extractable organic contaminants, or the molecular interaction of pollutants in soil in general, are among those research topics that will benefit greatly from MM methods today and in the future.

Acknowledgments

The authors thank the Austrian Science Fund (FWF) for financial support through the projects I4876–N (and DFG BO 5388/1–1), P30224–N34 and I3263–N34. The computational results presented have been achieved in part using the Vienna Scientific Cluster (VSC) under the projects “Application of computer simulation for soil bioremediation” No. 71170 and “Modeling of sorption processes at surfaces and interfaces of minerals and organoclays” No. 70544. We thank Wilfred van Gunsteren for designing the first versions of Figs. 1 and 2.

Abstract

The chapter focuses on Raman spectroscopy and its applications in soil analysis. Raman spectroscopy detects vibrational modes of molecules and finds wide applications in the detection of organic and inorganic components in soils. An upgraded version of Raman spectroscopy is surface-enhanced Raman spectroscopy (SERS), which plays a crucial role in the highly sensitive detection of trace elements present in soil samples due to its significant signal enhancement compared to Raman spectroscopy. Combined with other analytical tools and database algorithms, Raman spectroscopy and SERS provide specific and sensitive analysis for soil components and contaminants.

Key points

- The theory, principle, and mechanism of Raman spectroscopy and SERS are explained in detail.
- The differences between Raman spectroscopy and SERS are discussed.
- Important applications of Raman spectroscopy and SERS in the analysis of soil components and contaminants are reviewed.

Introduction

Raman spectroscopy studies the interactions between matter and light (electromagnetic radiation) as a function of the wavelength or frequency of the radiation. A fraction of incident radiation gets scattered upon interaction with molecules, atoms, electrons or phonons. There are different types of scattering, such as, Compton scattering, Brillouin scattering, Rayleigh scattering, and Raman scattering. Among them, Raman scattering plays an important role in the field of analytical applications due to its molecular fingerprinting capability. Raman scattering of electromagnetic radiation by molecules was predicted by Adolf Smekal using classical quantum theory in 1923 (Smekal, 1923). Later, C. V. Raman along with his co-researcher V. R. Krishnan experimentally proved the inelastic scattering phenomena in 1928 (Raman and Krishnan, 1928). When molecules are irradiated with monochromatic light, the radiation scatters in all directions. The majority of scattered radiation does not exhibit any change in frequency ($\Delta\nu$), i.e., the frequency of incident light (ν_i) is equal to that of the scattered light (ν_s), $\Delta\nu = \nu_i - \nu_s = 0$. This type of scattering is called Rayleigh scattering (Fig. 1). A tiny fraction (usually 1 part per 10 million) of the scattered radiation exhibits different frequencies or energy

Fig. 1 Jablonski diagram showing the origin of Rayleigh, Stokes and Anti-Stokes Raman scattering (A) and their distribution of frequency (B). Adapted with permission from Cho YC and Ahn SI (2020) Fabricating a Raman spectrometer using an optical pickup unit and pulsed power. *Scientific Reports* 10: 11692–11699.

levels compared to that of the incident radiation; this fraction is called Raman scattering which consists of two types of scattering (Cho and Ahn, 2020). When the molecules gain energy from the interacting radiation photon, i.e., the frequency of the scattered photon is smaller than that of the incident one ($\nu_s < \nu_i$). It is called Stokes Raman scattering and the change in frequency ($\Delta\nu_s = \nu_i - \nu_s$) is called the Stokes shift (Fig. 1). On the other hand, when the molecules lose energy to the interacting photon, the frequency of the incident photon is smaller than that of the scattered one ($\nu_i < \nu_{AS}$). It is called anti-Stokes Raman scattering and the change in frequency ($\Delta\nu_{AS} = \nu_{AS} - \nu_i$) is called the anti-Stokes shift (Das and Agrawal, 2011).

Raman spectroscopy

In general, Raman shifts are represented in terms of wavenumber ($\bar{\nu}$), i. e., the inverse of wavelength (λ) and directly proportional to energy (E). It has a unit of inverse length, i.e., cm^{-1} . The following formula can be used to establish the relationship between the spectral wavenumber and wavelength of a Raman spectrum. Typically, wavelength is expressed in nm. In this case, the final form of the relationship is as follows, where, λ_i is the wavelength of the incident radiation and λ_R is the wavelength of the Raman scattering.

$$\Delta\bar{\nu}(\text{cm}^{-1}) = \left(\frac{1}{\lambda_i(\text{nm})} - \frac{1}{\lambda_R(\text{nm})} \right) \times \frac{10^7 \text{ nm}}{\text{cm}}.$$

The following energy-level diagram (Fig. 1) explains different types of scattering derived from the interactions between incident radiation photons and sample molecules.

One of the most important criteria of a molecule to show Raman shift or to be Raman-active is its electromagnetic field-induced polarizability. Briefly, polarizability is defined as the tendency or ability of electron clouds of molecules to be distorted from their normal shape upon interaction with an external electromagnetic field. When a molecule is placed in the electromagnetic field, separation of charges, i.e., electrons and positive charges, happens, which is called induced dipole moment or polarizability (μ_i) (Gardiner, 1989). This induced dipole moment is directly proportional to the strength of the electromagnetic field applied (E). Therefore,

$$\mu_i = \alpha E$$

where α is the polarizability of a molecule, i.e., induced dipole moment per unit of the electromagnetic field applied (Gardiner, 1989). The change in polarizability is caused by the molecular vibrations induced by external interacting electronic vibration. The point to be noted is that, though large molecules have more vibrational modes ($3N - 6$), where N is the number of atoms, not all of the modes are equally Raman active. Some functional groups, for example, $-\text{S}-\text{S}-$, $\equiv\text{C}-\text{NO}_2$, $\equiv\text{C}-\text{S}-$, $\equiv\text{C}-\text{X}$ ($\text{X} = \text{F}, \text{Cl}, \text{Br}$

or I), $\text{—C}\equiv\text{N}$, and $\text{—C}\equiv\text{C—}$ exhibit Raman-active vibrational modes and strong changes in polarizability, leading to strong Raman signals (Hadjiivanov et al., 2021). In addition, symmetric stretches are more intense in Raman spectra. Therefore, molecular symmetry is considered as one of the major criteria for a molecule to be Raman-active. For example, $\text{N}\equiv\text{N}$ (N_2) is a symmetric molecule and thus Raman active. Therefore, a molecule having certain chemical bonding and symmetry exhibits characteristic vibrational frequencies, leading to distinct Raman peaks, which enables Raman spectroscopy to identify molecules (Dijkstra et al., 2005).

Raman spectroscopy has many advantages: (1) It provides both qualitative and quantitative information about the samples analyzed. Raman bands are the result of molecular vibrations after interactions with radiation. These vibrational modes are sensitive to even minor changes in chemical structure. Therefore, subtle differences in molecular environments are detectable. (2) Due to the noninvasive nature and fingerprinting capability, Raman spectroscopy has found applications involving non-destructive chemical analysis and microscopic imaging. Most Raman spectrometers use the radiation of visible or near-visible ranges, which can pass through transparent objects. Therefore, it is possible to scan samples even when they are sealed in transparent containers (i.e., glass or plastic vials and capillary tubes) or have viewing windows (i.e., temperature or pressure cells). (3) It requires small sample size and minimal sample preparation. For liquid samples, only a small volume (microliter or even nanoliter) is required for analysis. For solid samples, as long as the target regions are reachable to the microscope, Raman spectroscopy can be used to record the spectra on the samples directly. (4) Unlike infra-red (IR), Raman spectroscopy faces little to no interference by water molecules present in samples. This is because longer bonds scatter more photons based on the theory of light scattering. For example, molecules with long π -bonds (e.g., benzene) scatter a larger number of photons. On the other hand, water has small single bonds and is recognized as a weak Raman scattering molecule. (5) Raman detection is rapid, allowing spectral acquisition in seconds or even faster. These advantages helped Raman spectroscopy gain popularity in the detection and imaging of target molecules in different fields, such as pharmaceuticals, cosmetics, forensic science, geology, material science, and life sciences (Kuhar et al., 2018).

Though there are several advantages of using Raman spectroscopy as a tool to detect target analytes, it has several drawbacks that limit its wide application. First, Raman scattering is weak and detection cannot attain great sensitivity. Second, Raman spectroscopy suffers from fluorescence interference if the samples or sometimes impurities have background fluorescence signals that overshadow the Raman fingerprint region. To overcome these inherent problems, an improved version of Raman spectroscopy, known as surface-enhanced Raman spectroscopy (SERS) was developed.

Surface-enhanced Raman spectroscopy (SERS)

In 1974, Fleischman et al. observed for the first time a strong amplification of Raman signals derived from pyridine molecules adsorbed on roughened silver electrodes (Fleischmann et al., 1974). Subsequently, in 1977, van Duyne and co-workers coined the term surface-enhanced Raman spectroscopy (SERS) and carried out further experiments and validation (Jeanmaire and Van Duyne, 1977). Briefly, SERS is a phenomenon whereby Raman scattering is enhanced by many folds when the molecules are in the vicinity of plasmonic metal surfaces. In more technical terms, SERS is a phenomenon that involves both the plasmonic process (light–metal interaction) and vibrational spectroscopy (light–molecule interaction). When the incident light (laser) shines on roughened metal surfaces, especially noble metal nanostructures, the electromagnetic radiation drives the cloud of delocalized conduction electrons on the surface into collective oscillation. When the inherent oscillation frequency of the free electrons on the nanostructures matches with the frequency of the incident light, surface plasmon resonance (SPR) takes place. The SPR frequency varies depending upon the shape, size, electron-density, dielectric nature, and effective electron mass of the nanostructures. When the size of the nanostructures is smaller than the wavelength of the excitation light, confinement of surface plasmons happens and leads to localization of SPRs called localized surface plasmon resonance (LSPR) (Panikar et al., 2021). The nanostructures able to generate strong LSPR effects are called plasmonic nanostructures. They are usually made of noble metals, e.g., Au (gold), Ag (silver), or Cu (copper) (Das et al., 2021a, b). These noble metal nanostructures show brilliant colors in their colloidal solutions as the LSPR occurs at visible wavelengths. The LSPR helps resonant absorption as well as scattering of the incident radiation. Therefore, the incident light frequency is effectively coupled with the LSPR of noble metal nanoparticles, which largely enhances the magnitude of local electromagnetic field intensity at the nanoparticle surface. As a result, the original low intensity of Raman scattering of a molecule is enhanced (Fig. 2) upon adsorption at the vicinity of plasmonic nanostructures, leading to SERS (Jeanmaire and Van Duyne, 1977).

Though the exact working mechanism underlying the huge signal enhancement is often debated, principally there are two major driving forces behind the SERS signal enhancement. One is the electromagnetic field (EM) theory proposed by van Duyne and co-workers (Jeanmaire and Van Duyne, 1977), the other is a chemical enhancement (CE) theory suggested by Albrecht and Creighton (Albrecht and Creighton, 1977). The EM mechanism occurs when the incident light is exposed to the metal surface. If the frequency of the incident light is in resonance with surface conduction electrons, the collective oscillation enhances the strength of electromagnetic field in a specific area, called the plasmonic ‘hot spot’ (Stiles et al., 2008). The enhancement of Raman signals from molecules by the EM mechanism occurs when the molecules reside close to the hot spots and fall off rapidly with increasing distance from the surface (Jeanmaire and Van Duyne, 1977). The CE mechanism is related to the interactions between metal surfaces and chemisorbed molecules. The molecules adsorbed onto the metal surface generate charge transfer intermediates that can produce Raman excitation photons (Stiles et al., 2008). Overall, the EM mechanism is considered to be the dominant force, contributing 4–10 orders of magnitude over the CE mechanism, which contributes only 1–3 orders of magnitude in total

Fig. 2 A schematic illustration of the (A) collective oscillation of the free electrons after illuminating the nanoparticles with monochromatic light with resonance wavelength, (B) role of the electromagnetic and chemical enhancement factor in SERS. Adapted with permission from Panikar SS, Cialla-May D, De la Rosa E, Salas P, and Popp J (2021) Towards translation of surface-enhanced Raman spectroscopy (SERS) to clinical practice: Progress and trends. *Trends in Analytical Chemistry* 134: 116122–116142.

enhancement (Panikar et al., 2021; Stiles et al., 2008). In recent decades, SERS has evolved as an ultrasensitive vibrational spectroscopy technique to detect low-concentration analytes located on or near the surface of plasmonic nanostructures. It has found extensive uses in sensing various analytes directly attached to SERS substrates, such as biomolecules (e.g., proteins, nucleic acids, and pathogens), environmental contaminants, drugs, explosives, and adulterated foods (Das and Agrawal, 2011).

Conventionally, the analysis of soil components requires on-site sample collection followed by multi-step, complex, and time-consuming laboratory analyses. This process is labor intensive, time-consuming, and often costly because samples are collected and packaged on-site in the field, transported to the laboratory, and then processed following specialized protocols for analysis by specific instruments. To make the whole process of analysis simpler and less time consuming, molecular spectroscopic methods, especially Raman spectroscopy, could play beneficial roles. It enables rapid on-site analysis of samples with minimal sample collection and preparation, and provides quick, specific, and highly sensitive results. Conventional Raman spectroscopy can deliver information and data on the physico-chemical composition of components present in soil samples. Furthermore, it is possible to characterize multiple sample components simultaneously because of the narrow Raman spectral bands. One potential drawback of Raman spectroscopy when analyzing multiphase complex samples like soils, is interference of the intense background fluorescence signals coming from soil organic matter (e.g., humic substances), with the weak Raman signals. The SERS method can be used to address this problem because of the amplification of vibrational scattering of sample molecules by up to $\sim 10^{10}$ fold. Typically, Raman spectroscopy is most suitable for analyzing soil samples with high analyte concentration and low organic content due to the weak Raman scattering and strong fluorescence signals from soil organic matter (SOM). The SERS method can enhance Raman scattering many fold, which quenches fluorescence interference and allows the detection of low-concentration analytes with high sensitivity. Therefore, SERS methods have the potential to reduce the sample refinement process prior to analysis with its huge enhancement of the Raman signal and the ability to quench fluorescence. These are the reasons why regular Raman spectroscopy and SERS have found uses in many examples of analyzing soil components and contaminants.

Previous studies on the application of Raman spectroscopy and SERS in soil analysis can be classified into two categories: Analysis of soil components, and Analysis of soil contaminants. We will discuss these studies in detail in the following sections.

Application of Raman spectroscopy and SERS in the analysis of soil

Application of Raman spectroscopy and SERS in the analysis of soil components

In this section, we discuss potential applications of Raman spectroscopy and SERS to analyze different soil components, including soil organic matter, humic substances, phenolic compounds, and phosphorus.

Classification of soil samples

Soil classification is a crucial step in preparing for high quality cultivation. Luna et al. used Raman spectroscopy to differentiate soil types in Brazil (Luna et al., 2014). Five soil samples from different fields were collected and oven-dried followed by disaggregation through sieving. Soils were homogenized and compacted into tablet forms before analyses. For representative sampling, Raman scans were performed at 25 different points on each tablet-shaped sample within an area of $200\ \mu\text{m} \times 200\ \mu\text{m}$. Soil identification was achieved based on the fingerprinting of Raman spectra of the soils. They designed a robust characterization method for the soil samples utilizing Raman spectroscopy coupled with chemometric tools. The chemometric tools involve a genetic algorithm (GA) method and support vector machine (SVM). The combination of Raman spectroscopy and chemometric tools resulted in high specificity, sensitivity, and accuracy in the validation steps. Their method provides rapid differentiation of soil samples from different regions. High frequency regions of different Raman spectra indicate the presence of compounds with aromatic rings while the low frequency region of the Raman spectra reveals the presence of minerals and metal oxides (Fig. 3). The results obtained from their study detected elements that constitute oxides, humic compounds, and organic matter in metal complexes (Ca and Fe) in the soil samples tested. By integrating with chemometric tools, their method offers comprehensive information on the compositional features of the samples analyzed.

Analysis of soil organic matter

Soil organic matter (SOM) is one of the important indicators of soil quality and fertility. They play vital roles in water retention, nutrients cycling, and aggregate formation. Xing and coworkers combined Raman spectroscopy with Fourier-transform infrared-photoacoustic spectroscopy (FTIR-PAS) to predict SOM with the aid of partial least squares regression (PLSR) analysis (Xing et al., 2016). Composite samples were prepared by mixing the pure regional samples made of black soil, fluvo-aquic soils, paddy soils, and red soils from different regions of China. The composite soil was dried, sieved, and sampled in polythene bags prior to analysis. The soil samples were scanned from 180 to $3200\ \text{cm}^{-1}$ at room temperature for acquisition of Raman spectra with a portable Raman spectrometer (Fig. 4). They determined the optimal number of analytical factors by cross-validation, namely leave-one-out. They detected SOM with Raman spectroscopy and FTIR-PAS independently and obtained statistically significant values of R^2 and relative percentage difference (RPD) values; 0.75 and 1.96 (Raman) and 0.74 and 1.9 (FTIR-PAS) respectively for validation sets. The IR spectroscopy is often considered complementary to Raman spectroscopy as bonds that are Raman-inactive may be IR-active and vice versa. Therefore, they combined both for a more accurate analysis of the SOM. Compared to single application of Raman spectroscopy or FTIR-PAS, their combination made prediction of SOM more accurate with R^2 and RPD values of 0.81 and 2.18 , respectively for validation sets. A good fit for model analysis technically shows higher R^2 and RPD values. In conclusion, with the integration of Raman spectroscopy and FTIR-PAS an efficient and affordable detection of SOM is possible.

Humic substances and phenolic compounds are among the main components and active elements of the SOM. To determine the biological effects, it is important to analyze the chemical composition. The chemical structure and properties of the humic substances are not well-understood yet and are sometimes controversial. One thing is clear that there are different chemical

Fig. 3 Schematic diagram of the classification of soil samples based on Raman spectroscopy and X-ray fluorescence spectrometry combined with chemometric methods and the selection of variables. components comprising humic substances in soil. Humic substances play important roles in crop productivity, therefore research to determine their chemical composition and properties is much needed. With the help of SERS and Fourier transform infrared (FT-IR), Muscolo et al. observed the biological effects of humic substances, and water-soluble soil phenols on antioxidant activities, growth, proteins, carbohydrates, vitamins, and phenols in roots and shoots of *Pinus laricio* (Muscolo et al., 2020). Soil samples were collected under *Pinus laricio* trees on Mount Peripoli, San Lorenzo, Italy. KOH solution (0.1 M) was used to extract humic substances from the dried soil samples. The extract was incubated with colloidal silver for SERS measurements. The FT-IR and Raman spectroscopies were used in a complementary way to determine the chemical structure and composition of the humic substances. In general, the Raman scattering and FTIR absorption provide complementary information of molecular vibrations. The former is active for symmetric vibrations that alter the polarizability while the latter is functional for anti-symmetric vibrations that alter the dipole moment. The IR absorption spectroscopy, which is particularly sensitive to polar bonds such as O—H or N—H, is often used for identification of functional groups of molecules. On the other hand, Raman scattering spectroscopy, which is active for bonds such as C=C, C—S, or S—S, is applied to identify skeletal or framework structures of molecules (Hashimoto et al., 2019).

Analysis of soil phosphorus

Phosphorus content in soil is an important factor in promoting root growth, winter hardiness, maturity, and tillering in plants. Zheng et al. used Raman spectroscopy to detect phosphorus concentration in 15 sandy soil samples (Zheng et al., 2012). In this research, to achieve their objectives, they designed their project involving three sub-objectives, i.e., preparation of different types of sandy soil samples containing varying concentrations of phosphate, measurement of highly precise Raman spectra for soil samples in the same condition, and effective data processing to establish an accurate model to predict phosphorus concentration based on Raman spectra. Briefly, pure sandy soil (base soil) was leached to remove organic matter and nutrients. Calcium phosphate and mixed phosphates were added to the base soil. The mixture was dried to prepare final soil samples containing different phosphate concentrations. They measured the signature Raman spectra of phosphorous content in the soil sample and derived a relationship between the concentration of phosphorus and their corresponding Raman spectra. All Raman spectra of soil samples were acquired within the wavenumber range of 239 cm^{-1} to 4045 cm^{-1} with a resolution of 4 cm^{-1} and integration time of 20s. Furthermore, they established a partial least squares (PLS) model to predict phosphorus concentration in the soil. It was also found that different phosphate compounds showed different Raman intensities at a fixed concentration of phosphate. The order of Raman intensity was aluminum phosphate > mixture of phosphates > magnesium phosphate > calcium phosphate. The phosphate Raman bands ranged from 345 cm^{-1} to 545 cm^{-1} and from 1311 cm^{-1} to 1402 cm^{-1} . Their analysis showed a good coefficient of determination (R^2) both for calibration ($R^2 = 1$) and validation ($R^2 = 0.937$), indicating that the method is promising for detecting varying concentrations of phosphorus in soil samples.

Application of Raman spectroscopy and SERS in the analysis of soil contaminants

In this section, we discuss major applications of Raman spectroscopy and SERS-based techniques for the analysis of soil contaminants, including various organic and inorganic ones such as thiram, organophosphorus pesticides, chlorpyrifos, thiabendazole, persistent organic pollutants (POPs), and various heavy metals.

Analysis of organic contaminants in soil

Detection of thiram in soil

Organic contaminants can be released into soils due to agricultural activities, such as pesticide applications, or industrial and municipal waste disposal, such as bio solids from wastewater treatment plants. Thiram is one of the major pesticides used to prevent crop damage and deterioration during storage or transport. Due to potential environmental issues caused by off-target exposure, detection of thiram in soil samples is crucial to evaluate its concentration and impact on soil safety. Zhang et al. reported a novel SERS technique to detect thiram selectively and sensitively in soil (Zhang et al., 2017). They developed a SERS substrate using triangular silver nanoparticles (TSNPs) of suitable nano size (29 nm) and with sharp corners to detect thiram residue in soil samples (Fig. 5). The soil samples collected were powdered, dried, and mixed with different concentrations of thiram. Ethanol was used to extract thiram from the soil and centrifuged to obtain the thiram rich supernatant. Finally, soil extracts containing different concentrations of thiram were mixed with TSNP colloids. The thiram-containing TSNPs were scanned under a Raman spectroscopy. Due to their strong SERS signal enhancement, it was found that the limit of detection (LOD) value was lower than the LODs obtained by other SERS substrates, including nanocubes and nanospheres. Their method exhibited good linearity in the concentration range of 0.12 to $4.8\text{ }\mu\text{g g}^{-1}$ and a low LOD of 90 ng g^{-1} . The results show great potential and applicability of TSNPs as novel SERS substrates in the detection of pesticides in soil samples.

Detection of organophosphorus pesticides in soil

Guselnikova and co-workers developed a surface plasmon polariton (SPP)-supported and a metal–organic framework compound (MOF-5)-coated gold nanosubstrate for selective, reproducible, and highly sensitive SERS detection of organophosphorus pesticides (Guselnikova et al., 2019). The MOF-5 is a class of metal–organic framework compounds with the formula $\text{Zn}_4\text{O}(\text{BDC})_3$, where BDC stands for 1,4-benzodicarboxylate. Due to the unique porous structure, MOFs were used to absorb pesticide molecules

Fig. 5 Synthesis of highly plasmonic small and sharp triangular silver nanoplates utilizing tiny triangular nuclei with their excellent SERS activity for selective detection of thiram residue in soil. Adapted with permission from Zhang C-H, Zhu J, Li J-J, and Zhao J-W (2017) Small and sharp triangular silver nanoplates synthesized utilizing tiny triangular nuclei and their excellent SERS activity for selective detection of thiram residue in soil. *ACS Applied Materials & Interfaces* 9: 17387–17398.

efficiently and enhance their analytical signals. The immobilization of MOFs on the plasmon-active surface can promote selective entrapping of the analyte molecules, increase utilization of plasmonic hot-spots as well as enhance molecular resonance phenomena, through the charge transfer between the MOFs and analyte molecules. The SPP is a modified version of surface-plasmon resonance (SPR) and it involves both charge motion on the metal surface (surface plasmon) and electromagnetic propagation in air or a dielectric medium (polariton). In particular, SPPs are electromagnetic waves that originate at and travel along the interfaces of plasmonic materials and dielectric materials, practically in the range of infrared or the visible frequency. As the soil analysis was performed in a gold–air interface, a large number of SPPs were generated and enhanced SERS signals were observed when organophosphorus pesticides were detected. They used simulated soil samples composed of homogenized soil, organophosphate pesticides, and water. The mixture was vortex-mixed and dried. The dried soil samples were again suspended in water before centrifugation. The supernatants were collected and incubated with the MOF-based SERS substrate for spectroscopic studies. High reproducibility of SERS signals was achieved due to the homogeneous distribution of surface plasmons along the Au surface (Fig. 6). The developed gold and MOF-based SERS substrate performed well to detect organophosphorus pesticides with a low limit of detection (up to 10^{-12} M). Apart from organophosphorus pesticides, other organic contaminants, e.g., mycotoxins, and azo dye from spiked soil samples were also detected by the SERS substrate. The method is suitable for on-site detection since the detection was carried out by a handheld Raman spectrometer.

Detection of chlorpyrifos in soil

Chlorpyrifos (CPF) is a well-known pesticide, widely used to prevent and control crop-pests and diseases, though its excessive use causes environmental pollution. Compared to the traditional methods to analyze pesticides in soil samples, SERS-based techniques have gained credibility due to their ultrasensitive and specific detection ability. He et al. used gold nanoparticles of different sizes as SERS substrates to determine the concentration of CPF residue in soil (Fig. 7) (He et al., 2019). In their study, first, CPF solutions of different concentrations were mixed with the soil samples. The CPF residue was extracted from the soil samples following the QuEChERS method. Briefly, the soil sample was homogenized, dissolved, and centrifuged. Then the supernatants were put through a solid phase extraction process. The extracts were then incubated with the gold nanoparticles before SERS measurements. It was found that with increasing CPF concentration from 0.025 to 9.54 mg kg⁻¹, the characteristic SERS peaks of CPF at 674 cm⁻¹ (benzene ring), 610 cm⁻¹ (C-Cl), and 529 cm⁻¹ (P=S) increased gradually. Moreover, the AuNPs prepared enabled ultra-sensitive and reproducible SERS analysis yielding a limit of detection (LOD) as low as 10 μg L⁻¹ in the spiked soil sample. With real soil samples and using the partial least squares regression (PLSR) model, the LOD of CPF residue was as low as 0.025 mg kg⁻¹ with a coefficient of determination (R^2) of 0.977. With a simple method to synthesize gold nanoparticles as SERS substrates with ultra-sensitivity and high reproducibility, the SERS method is very promising to determine pesticide residues in soil.

Detection of thiabendazole in soil

Thiabendazole (TBZ) is widely used as an antifungal, antiparasitic, and preserving agent to treat downy mildew, sclerotium blight, as well as root rot diseases in plants. Nonselective and excessive use of TBZ creates excess accumulation of pesticide residues in soil, leading to environmental pollution and soil compaction. Therefore, it is an important task to monitor TBZ concentrations in soils. Nie et al., used gold nanoparticles as a SERS substrate to enhance Raman signal intensity and determined the presence of TBZ

Fig. 6 A layer of MOF-5 is synthesized on the plasmonic gold grating. Porous MOF-5 absorbs organophosphate pesticides and they are detected by their SERS signal. Adapted with permission from Guselnikova O, Postnikov P, Elashnikov R, Miliutina E, Svorcik V, and Lyutakov O (2019) Metal-organic framework (MOF-5) coated SERS active gold gratings: a platform for the selective detection of organic contaminants in soil. *Analytica Chimica Acta* 1068: 70–79.

Fig. 7 The Raman spectra of CPF with gold nanoparticles at different concentrations (A) ranging from 0.01 to 10 mg L⁻¹, linear equation of Raman characteristic peak intensity and its concentration (B) at 530, 560, 610, 674 cm⁻¹ of the CPF molecule. Adapted with permission from He Y, Xiao S, Dong T, and Nie P (2019) Gold nanoparticles with different particle sizes for the quantitative determination of chlorpyrifos residues in soil by SERS. *International Journal of Molecular Sciences* 20: 2817–2828.

quantitatively in red soil extracts (Nie et al., 2018). The target analyte TBZ was extracted using solvent dissolution followed by soil matrix removal by centrifugation and membrane filtration. The TBZ-treated soil extracts were further incubated with plasmonic gold nanoparticles for SERS measurements. Their analysis showed the characteristic Raman peaks of TBZ in soil are at 784, 1008, 1270, 1328, 1406 and 1576 cm^{-1} . They calculated a limit of detection (LOD) value that reached 0.1 mg L^{-1} based on the peak at 784 cm^{-1} characteristics of the $\delta(\text{C—H})$ bond. A linear correlation between TBZ concentration in soil and Raman peak intensity was observed ($R^2 = \sim 0.995$) with a limit of quantification (LOQ) up to 1 mg L^{-1} . Overall, their technique was able to detect TBZ quantitatively in the soil extracts.

Detection of persistent organic pollutants in soil

Persistent organic pollutants (POPs), e.g., polychlorinated biphenyls (PCBs), polychlorinated benzene, and dioxins are major environmental pollutants and hazards to human health. Jency et al. reported a simple method to detect PCBs in soil samples using SERS with the help of β -cyclodextrine (β -CD) functionalized gold nanoparticles as the SERS substrate (Arockia Jency et al., 2015). The POP polluted soil samples collected from agricultural fields were ground into powder and sun-dried. Acetone was used to extract POPs from soil samples. The transparent supernatant was taken and incubated with the β -CD conjugated gold nanoparticles for SERS experiments. The β -CD is widely used in chemistry and pharmaceutical research for their ability to improve the solubility and stability of compounds with very low solubility in water. The β -CD molecules have a cavity at the center of the molecular arrangement and can thus form stable inclusion complexes with the analytes. The SERS spectral analysis showed that the functionalized gold nanoparticles of small size (9 nm) and large surface area exhibited strong SERS activity as collectively they produce more plasmonic junctions or SERS 'hot spots.' The C—H in-plane bending and C—C stretching modes suggested that the PCBs were adsorbed on the β -CD gold nanoparticle surface in a stand-on orientation. When the contaminated soil samples were added to AuNP- β -CD, the binding of PCB molecules with β -CD resulted in the aggregation of gold nanoparticles due to change in the medium hydrophobicity. This phenomenon produced excellent Raman signal enhancement. This method has the potential to detect PCBs, and to facilitate risk assessment and the removal of these hazardous materials from the environment.

Analysis of inorganic contaminants in soil

Detection of vivianite arsenates in soil

Soil contamination by inorganic chemical species, such as heavy metals, is of great concern due to their considerable effects on soil quality and safety. Arsenic compounds are often prevalent in soils because of their presence in mine tailings, cattle dips, or wood preservatives. Long-term persistence of arsenic compounds in soils together with their leachates can sometimes be strongly reactive and mobile, leading to the formation of highly stable metal arsenate compounds. One of such arsenate minerals is vivianite. Frost et al. used Raman spectroscopy to characterize vivianite arsenates in soil (Frost et al., 2003). Soil samples contaminated with vivianite arsenates of different divalent metal ions were ground, dried and placed on a polished metal surface on the stage of a Raman microscope. Raman spectroscopy enabled the identification of spectral bands corresponding to the mineral phosphate and arsenate units. Each mineral exhibits its own characteristic Raman spectrum that enables ready and rapid identification of the mineral type. For example, as the most common class of arsenic compounds available in soil as contaminants, vivianite arsenate has a characteristic Raman spectral band at 951 cm^{-1} .

Detection of harmful metalloids in soil

Soil water contaminated by mining and acid mine drainage often possesses high levels of harmful metalloids, some of them, e.g., Pb (lead), Cd (cadmium), and As (arsenic), are potentially dangerous due to their toxicity. Experts often use limestone fillers to immobilize the elements through adsorption and precipitation owing to its large content of carbonate and low cost. Pérez-Sirvent et al. analyzed fillers with the help of Raman spectroscopy and X-ray diffraction and reported that the former technique was more beneficial for assessing the physicochemical behavior of the fillers (Pérez-Sirvent et al., 2019). First, the heavy metal ions were absorbed into the porous limestone fillers which worked as a matrix for the metal ions. Then, the Raman spectra of the absorbed ions were collected and compared to the crystalline ones as references. After the absorption process, the heavy metal salts formed new bonds with the filler materials, which generated greater Raman intensity. This is how the presence of heavy metals and metalloids were detected by Raman spectroscopy. For example, As formed an As—O—H bond on absorption by filler material and showed a more intense band at 1088 cm^{-1} . Raman spectroscopy was found to be a very useful tool to monitor the process of sorption of potentially harmful metalloids (precipitation for Cd^{2+} , Pb^{2+} , Zn^{2+} , Cu^{2+} and adsorption for As^{5+}) on limestone filler surfaces because the percent increment was calculated from the characteristic Raman spectral bands. One of the drawbacks of the method is that it is qualitative.

Detection of lead in roadside soil

One interesting application of Raman spectroscopy is the detection of vehicle-released pollutants in roadside soils and plants. Carrero et al. carried out a study to assess the effects of urban pollutants on roadside soils and to understand the release mechanism of the metals (Carrero et al., 2012). They selected soils, guardrails, and plants near to busy roads in the urban area of Bilbao, Spain. The contaminated soil samples were powdered, dried, and placed on a plate for Raman measurements. For example, Spain banned leaded gasoline in 2001, but they found accumulated lead (Pb) in roadside soils during the study in 2011. Raman and energy dispersive X-ray fluorescence (m-ED-XRF) analysis of the selected soil sample indicated the presence of litharge (PbO). This type of

lead compound is not easily removed and accumulates in the top layer of soil. Therefore even after phasing out leaded gasoline more than a decade before, a large concentration of Pb was detected. Their analysis was a qualitative one, but it was able to detect litharge in the roadside soils.

Detection of Zn(II) in soil

Soil contamination by heavy metals is a common hazard faced by many industrially developed and developing countries. Szabó et al. reported a novel method for the detection of heavy metals with the help of SERS techniques (Szabó et al., 2011). As metal ions do not exhibit Raman signals by themselves, a chelating agent 4-(2-pyridylazo) resorcinol (PAR) for Zn(II) was used to determine SERS spectra of the Zn(II)-PAR complex in contaminated soil samples. To enhance the detection limit, they attached the chelate complex to a SERS substrate, silver colloid. The Zn(II) ions were extracted from the soil by the acid–water solvent extraction method. When PAR was added to the extracted solution, the color of the solution turned red indicating the formation of a metal-PAR complex. Then the Zn(II)-PAR extract solution was added to the silver colloid. The color of the silver colloid changed to green, indicating adsorption of the Zn(II)-PAR on the silver surface. The PAR on complex formation with Zn(II) gives rise to a new Raman peak at 1335 cm^{-1} . The Raman spectra of PAR alone, the Zn(II)-PAR chelate complex, and PAR–soil mixture were recorded. The SERS spectra of Zn-contaminated soil extracts and the Zn(II)-PAR standard complex were in good accord in terms of spectral profile and band position. They used SERS of the Zn(II)-PAR complex to detect Zn(II) in the contaminated soil samples and later on quantified its concentration with UV–Vis spectroscopy. The Zn(II) concentration in the contaminated soil was determined (390 mg kg^{-1}) which is in good agreement with the standard values reported by the Romanian Environmental Protection Agency. In the current paper, the authors reported that the UV–Vis spectra cannot distinguish between two different heavy metals of a PAR complex, e.g., Zn(II) and Cu (II). They did not provide any explanation as to why SERS was not used for the quantitative detection of Zn(II), especially given that it is a more sensitive and molecular-selective tool than UV–Vis.

Conclusion and outlook

This chapter covers the fundamental principles and mechanisms of Raman spectroscopy and SERS, and their applications in soil analysis. Raman spectroscopy is a spectroscopic technique that detects vibrational modes of molecules. In general, it is a non-invasive chemical analysis technique providing in-depth data and information about the chemical composition, concentration, and structure. Raman spectra are used to extract unique ‘fingerprint’ vibrational modes of the sample molecules and provide chemical, physical, and structural properties of the molecules. Raman spectroscopy has several advantages, including its suitability for analyzing a wide range of inorganic and organic molecules, non-invasive analysis, no water interference, minimal sample preparation, and small sample size requirement. These are the reasons why Raman spectroscopy has been used in many instances for analyzing soil components and contaminants. Despite the above-mentioned advantages, there are also several major disadvantages, i.e., weak signal intensity leading to lower sensitivity and the background fluorescence signals of impurities that overshadow the Raman peak of target molecules. To overcome the limitations, an advanced technique based on surface plasmon resonance of the plasmonic nanostructures was introduced, i.e., surface-enhanced Raman spectroscopy (SERS). The SERS enabled by plasmonic nanostructures (typically noble metal nanoparticles) demonstrates strong selectivity, specificity, and sensitivity, allowing detection of a wide range of soil components and contaminants.

Although a variety of methods based on regular Raman spectroscopy and SERS have been reported for the detection of soil components and contaminants, there are several voids to be filled in the future.

1. Given that two major limitations of Raman spectroscopic methods, i.e., weak sensitivity and background fluorescence signals, SERS has emerged to be a better alternative to Raman spectroscopy. Therefore, development of novel SERS substrates with a greater signal enhancement factor (EF) should be a major point of focus in future. High EF could overshadow background signals coming from impurities. Moreover, SERS substrates with higher EF values (beyond $\sim 10^7$) could achieve limits of detection (LODs) below nanomolar concentrations of the target analytes.
2. The confocal Raman imaging technique, which has not been used for soil analysis previously, could be applied as a potential technique to investigate the spatial distribution of soil components. The technique was used successfully for analyzing the spatial distribution of proteins and phenolic compounds in grains (Piot et al., 2000) as well as silver nanoparticles adsorbed by hydrated minerals (Brittle et al., 2018). It is rapid and noninvasive without complicated sample preparation. The technique uses Raman bands as spectral markers to construct distribution maps of chemical species. High spatial resolution of the Raman mapping technique reveals chemical and molecular heterogeneity within 3-D samples. Thus, different spatially distributed components of soil samples can be chemically as well as structurally analyzed by the technique.
3. Raman spectroscopy and SERS-based techniques acquire a large number of vibrational spectra from a mixture of complex components during analysis or imaging. Classical linear methods of data processing are no longer adequate for analyzing data of complex systems. Advanced multitasking machine learning methods are required. In recent years, machine learning has found potential applications in analytical science by extracting information from big and complex datasets in spectroscopy. Various machine learning methods have been used to analyze food colors, additives, meat types in complex food samples, biomolecules (proteins, lipids) present in cancer tissue samples, and illicit drugs present in forensic samples (Lussier et al., 2020). Soil samples are extremely complex in nature containing organic, inorganic, biotic, abiotic, solid, gaseous, and liquid components. Therefore,

suitable machine learning techniques in combination with Raman spectroscopy and SERS tools are promising to provide specific analysis of the components in complex soil samples in the future.

4. A Raman spectroscopy and SERS based 'soil-on-chip' microfluidic platform is expected to be a breakthrough technology in soil analysis. Though still in its infancy, microfluidic soil chip or 'soil-on-chip' techniques allow direct spectroscopic analysis of soil components and contaminants in well-controlled microfluidic channels (Stanley et al., 2016). Raman spectroscopy and SERS can play a major role as a technique in 'soil-on-chip' application due to their strong signal enhancement, small sample volume requirement, and noninvasive nature of analysis. The proposed 'soil-on-chip' sensing platform has the following potential applications: (i) determination of spatial and time resolved distribution, transport, and transformation of organic and inorganic pollutants in soil, (ii) analysis of SOM dynamics to understand soil carbon storage more comprehensively, (iii) identification and classification of soil microbes, and (iv) understanding chemo taxis of soil microbes at the micro scale spatial resolution.
5. Another important future aspect is the integration of SoilCards with Raman spectroscopy/SERS techniques. SoilCards are paper-based test-strips that analyze plant nutrients in a quick, easy, and affordable fashion, especially for underprivileged farmers without access to soil testing laboratories. These paper strips detect basic soil nutrients (N, P, K) and pH of the soil samples through visible color changes for corresponding elements. A combination of SERS nanosubstrates with the conventional strips could enhance their sensitivity and detection ability many fold, which should be explored in the future.

Abstract

Fourier transform infrared (FTIR) spectroscopy is a vibrational spectroscopy that is useful in the study of a wide range of soil chemical processes. Topics included in this chapter include a brief explanation of the theory of molecular vibrations, a survey of useful vibrations for soil scientists, a description of different experimental approaches to measuring FTIR spectra, and current examples of using FTIR spectra to answer field and laboratory based soil chemical research questions.

Key points

- FTIR spectroscopy is useful in studying soil minerals, organic matter, and adsorption processes on soil surfaces.
- A variety of FTIR sampling approaches (diffuse reflectance and Attenuated Total Reflectance) are popular for soil samples.

Introduction

Fourier transform infrared (FTIR) spectroscopy is a form of vibrational spectroscopy that is useful in the study of a variety of soil chemical processes. In the mid-infrared (mid-IR) range, vibrations arise from many environmentally important molecules such as organic acids, soil organic matter, mineral phases, and oxyanions (Johnston et al., 1996). It is possible to utilize FTIR spectroscopy as a quantitative analytical method and also as a tool to determine bonding mechanisms in solids and on surfaces. Molecular vibrations can be related directly to the symmetry of molecules, and so it is often possible to determine precisely how a molecule is bonding on surfaces or as a component in a solid phase from its infrared spectrum. Many experimental methods exist for probing samples in various states and at different spectral regions.

The nature of molecular vibrations

The infrared region of the electromagnetic spectrum lies between 10 and 10,000 cm^{-1} , which can be expressed as a frequency of 10^{12} – 10^{14} Hz. This frequency overlaps with the frequency of molecular vibrations. When infrared radiation is at the same frequency as a molecular vibration, it can induce a transition to a higher energy state. This transition will only occur if it induces a dipole. A true molecular vibration is defined as a movement of the atoms of a molecule that do not change the center of mass and that involve no rotation. Vibrations that obey this definition are known as the ‘normal modes.’ For a nonlinear molecule, the normal modes may be due to symmetric or asymmetric stretching, and in-plane or out-of-plane bending. Not all of a molecule’s normal-mode vibrations will be active when subjected to infrared energy. Rather, the symmetry of a molecule will affect the position and number of infrared-active peaks.

Infrared peaks of interest

In the mid-IR range ($400\text{--}4000\text{ cm}^{-1}$), there are several extremely important and useful classes of bonds that can be studied. The FTIR spectroscopy has been used extensively by both geologists and soil scientists to study clay minerals and other inorganic soil components. The structure of minerals can substantially affect their infrared spectra, and entire textbooks are available with tables of peak positions and figures containing spectra of reference minerals (e.g. Farmer, 1974). Water has an intense infrared absorbance in the mid-IR region, which typically is considered a limitation of the technique for environmental research. However, the strong absorbance of water bands has been exploited by researchers who investigated the effects of humidity changes on self-supported films of clay minerals.

Many organic compounds also have diagnostic peaks in the infrared region, and FTIR has been used to study the nature of soil organic matter as well as the adsorption of organic acids. Many metals and metalloids form negatively charged oxyanion molecules in aqueous solution, and FTIR spectroscopy has been used extensively to study their adsorption and precipitation reactions. Fig. 1 contains infrared spectra from selected experiments using FTIR to study reactions of: (1) natural organic matter (NOM), and (2) inorganic minerals in soils. Infrared absorbance bands in Fig. 1a have been labeled to show how changes in functional-group makeup can give rise to new infrared peaks. Also notice how many of the peaks in the NOM disappear or shift in position when NOM is adsorbed on to a mineral surface. This is due to chemical bonding with carboxylic and phenolic NOM groups and the iron oxide surface. In Fig. 1b, a mineral transformation is monitored using FTIR spectroscopy. The initial $\gamma\text{-Al}_2\text{O}_3$ solid phase is not stable in water, and over the 2.5-month experimental period it transforms into a crystalline gibbsite $\text{Al}(\text{OH})_3$ phase.

Infrared spectral analysis

A detailed analysis of the theoretical infrared spectrum from first principles is not always required. It is possible simply to compare unknown samples to those of spectra with known molecular configurations to determine the structure of an

Fig. 1 (a) Infrared spectra of natural organic matter in water compared with natural organic matter (NOM) adsorbed on an iron oxide. (b) Infrared spectra of $\gamma\text{-Al}_2\text{O}_3$ aged from 3 to 75 days. The peak at 1027 cm^{-1} is due to transformation of the initial Al_2O_3 into a crystalline gibbsite phase. Adapted from Wijnja H and Schulthess CP (1999) ATR-FTIR and DRIFT spectroscopy of carbonate species at the aged $\gamma\text{-Al}_2\text{O}_3$ – water interface. *Spectrochimica Acta. Part A Molecular and Biomolecular Spectroscopy* **55**(4): 861–872, with permission.

unknown. This is referred to as spectral fingerprinting. This technique relies on one's ability to synthesize reliably reference compounds of known chemical structure or obtain their spectrum from a library. This approach is reasonably straightforward in the case of organic molecules, as large commercial software spectral libraries are available. In the case of unknown inorganic spectral identification, however, suitable standards can often be difficult to synthesize, and aqueous standards are often present as mixtures of species. For these reasons, assigning peaks based on rules from molecular symmetry is often necessary.

Symmetry rules assign a molecule to a unique point group based upon the arrangement of its atoms in space (Nakamoto, 1986). A common example of how infrared spectra may be related to molecular symmetry is the case of sulfate. The FTIR spectroscopy has been used by many researchers to study sulfate bonding in mineral structures and as surface adsorption complexes. The clear relationship between the molecular symmetry of sulfate species, its point group, and its infrared spectrum is an example of the utility of this approach. In the case of aqueous sulfate, there are two normal modes that are accessible to spectroscopic investigation. They are the nondegenerate symmetric stretching ν_1 , and the triply degenerate asymmetric stretching ν_3 bands. As a free anion in solution, sulfate has tetrahedral symmetry and belongs to the point group T_d . For this point group, only one broad peak, due to the ν_3 stretch, is observed at approximately 1100 cm^{-1} . If sulfate is covalently bonded to one or more cations, the symmetry is lowered, a ν_1 peak becomes infrared active, and the ν_3 band splits into more than one peak. When sulfate is bound as a monodentate complex, the ν_3 band splits into two peaks, while the ν_1 band becomes fully active at approximately 975 cm^{-1} , and C_{3v} point group symmetry results. If sulfate forms a bidentate binuclear (bridging) complex, the complex's symmetry is decreased to C_{2v} , and the ν_3 band splits into three bands between 1050 and 1250 cm^{-1} , while the ν_1 band is usually shifted to a higher wave number. The relationship between molecular symmetry and the number and position of infrared peaks is detailed in Fig. 2. Sulfate is typical of tetrahedral oxyanions, and so the relationship also may be readily extended to other tetrahedral oxyanions of environmental relevance (such as chromate, selenate, phosphate, and arsenate).

Similar rules may be derived for molecules of other point groups also, making the symmetry approach very powerful in the assignment of molecular configuration from FTIR spectra. However, one must be aware that infrared peaks may arise from many potentially occurring molecular vibrations. Of particular concern in environmental science is the fact that interactions with protons and water molecules will substantially affect the infrared spectrum of sulfate, not only when covalently bound to sulfate (as bisulfate or sulfuric acid), but also when hydrogen bonds are formed with waters of hydration. To improve peak assignment in such cases, experiments are usually repeated in D_2O (heavy water) as a solvent. Substitution of D (deuterium) for H (hydrogen) in surface complexes or mineral structures will shift the position of infrared peaks, while peaks that do not involve protons are unaffected. It is also possible to calculate theoretical infrared spectra using molecular modeling software. The absolute position of peaks may not be correct, but trends in how species are affected by the presence of protons or metals are still quite helpful in peak assignment.

Fig. 2 Relationship between molecular symmetry and infrared spectra for aqueous, monodentate, and bidentate sulfate species. Adapted from Peak D, Ford RG, and Sparks DL (1999) An in situ ATR-FTIR investigation of sulfate bonding mechanisms on goethite. *Journal of Colloid Interface Science* **218**: 289–299.

FTIR as a quantitative tool

The infrared absorbance of a molecular vibration obeys the Beer-Lambert law. This means that FTIR spectroscopy, if properly calibrated, is a quantitative technique. The relationship is as follows:

$$A = \epsilon bC, \quad (1)$$

where A is absorbance, ϵ is the molar absorptivity coefficient, b is the thickness of the sample (or pathlength), and C is the concentration of the molecule in the sample. Note that ϵ is specific to a given vibration, and that A is typically reported in terms of peak height or integrated absorbance from a fitted peak. Changes in sample configuration (transmission vs. reflectance) for different types of FTIR experiments can quantification require spectral transformations or correction factors.

Instrumentation

FTIR refers to a class of spectrometers that are distinguished from older, double-beam infrared units by their use of a single beam and an interferometer and detector to collect simultaneously a spectrum over the entire wavelength of interest. These raw data, called an interferogram, are an oscillation over time that can then be converted to a function of frequency, as in a traditional infrared spectrum, by a mathematical procedure called Fourier transformation. The FTIR instruments have largely replaced older double-beam units because they have better spectral resolution, allow for much more rapid data collection, and have an improved signal-to-noise ratio.

Common experimental techniques

Several different FTIR experimental techniques are commonly employed by environmental researchers. These are transmission mode experiments with pressed disks, diffuse reflectance experiments with powder samples, and attenuated total reflectance studies with aqueous solutions and hydrated suspensions. The primary differences in the commonly used techniques are: (1) the amount of sample preparation that is required, (2) the spectral range that is accessible to the technique, and (3) the detection limits. Each technique may be particularly well suited to certain research questions, and more than one technique is sometimes required.

Transmission-mode measurements

Transmission-mode experiments are both the simplest and most common type of FTIR experiment. Samples are diluted in some medium and placed perpendicular to the infrared beam. A detector measures the amount of infrared beam that is transmitted through the sample. To obtain the spectrum of only the sample, the spectrum of the pure medium is first measured and used as a reference. A spectrum of the sample in the medium is then collected and the ratio to the reference determined to obtain the spectrum of the sample. A typical experimental configuration for transmission-mode experiments is shown in Fig. 3.

Fig. 3 Common sampling methodologies for transmission-mode, diffuse reflectance (DRIFT), and attenuated total reflectance (ATR) Fourier transform infrared experiments. I_0 , energy prior to the sample; I , energy after the sample; D_p , depth of penetration through the sample.

Solid samples are typically diluted to 1–2% wt in KBr (potassium bromide) salt and then made into a thin disk with a press. The final product is a thin, clear disk that is placed in a sample holder and analyzed. For transmission mode experiments to be successful, water must be removed from the system, so samples are heated to remove as much water as possible prior to dilution. Care must be taken with amorphous and unstable solids to avoid transformations that may occur at elevated temperatures. Organic materials can also often be studied in transmission mode by simply placing them in a thin liquid cell. The solvent should have a relatively low infrared absorbance and should not have infrared peaks that overlap with those of the organic compounds of interest.

Transmission-mode experiments can provide quantitative information more easily than some other experiments because Beer's Law is directly applicable. The path length through the sample must be known, and molar absorptivity can be determined by collecting spectra at several known concentrations and constructing a calibration curve. Once the path length and molar absorptivity are known, concentration and absorbance can then be determined.

Example of transmission experiments

This technique has been quite useful historically for soil scientists who are studying mineral transformations or who need to determine quantitatively the mineral composition in unknown samples. However, the technique involves substantial sample modification (removal of water by drying and vacuum; physical mixing with KBr) that may change the structure of both solid phases and adsorbed surface species. Particularly in complex systems, such as soils, the peaks of minor components such as clay minerals may be masked by other species of higher concentration such as quartz.

Recent advances in analytical capabilities have led to a resurgence in transmission mode FTIR spectroscopy as an important part of field-based soils research. Improved software packages designed to handle large spectral datasets and statistical approaches that determine correlation coefficients and principal components in those datasets now make it possible to deconvolute large (thousands and greater) datasets of transmission mode infrared spectra. In addition, advances in high throughput FTIR have made it possible to collect this quantity of spectra in a reasonable time frame. The limitation of these approaches is typically the preparation of KBr pellets for measurement.

Diffuse reflectance infrared Fourier transform experiments

The diffuse reflectance technique was developed partly to address some of the shortcomings of the pressed-disk method of sampling, and also to extend FTIR spectroscopy to additional types of samples. Many substances, particularly powders, scatter light in all directions in a diffuse manner. The diffuse reflectance technique isolates the portion of the infrared light that is scattered diffusely from that which is either transmitted or specularly (regularly) reflected and collects it as a diffuse reflectance spectrum. A typical experimental configuration for transmission-mode experiments is shown in Fig. 3. The DRIFT spectroscopy is conducted only on powder samples. Samples may be used neat (with no dilution), or diluted with a non-absorbing matrix such as KBr. Samples are typically ground with a mortar and pestle to avoid large particles with flat surfaces that may distort the spectrum by exhibiting specular reflectance. Samples are not pressed into disks as with transmission experiments, but are simply packed into a sample holder. This makes the collection of DRIFT spectra somewhat simpler than transmission-mode experiments. It also avoids changes in sample structure that may occur when subjected to elevated pressure. However, quantitative DRIFT studies are more difficult than transmission-mode IR, because steps in sample preparation can substantially affect a diffuse reflectance spectrum. Specifically, the particle size, the sample homogeneity, and the degree of packing will influence the results.

Regardless of the care taken in sample preparation, DRIFT data differ from data obtained in a transmission-mode experiment. Peak intensities at higher wave number are typically compressed, and all peak shapes tend to be rather rounded compared with the sharp peaks from pressed disks. A mathematical correction can be applied to the raw spectra to compensate for these anomalies and make DRIFT data directly comparable with transmission-mode references. This conversion is known as the Kubelka-Munk equation, and the FTIR control software typically can perform this conversion automatically.

The primary advantage of DRIFT over transmission-mode studies is that sample preparation does not require the pressing of disks. This means samples can be prepared more quickly and with less effort. However, samples are still dried and diluted in salts, therefore, sample preparation may still affect the chemical species in an environmental sample. The primary drawback of DRIFT is that it trades ease of sample preparation and ability to observe weaker bands by the analysis of neat samples for additional complexity in quantitative analysis.

Attenuated total reflectance experiments

The attenuated total reflectance (ATR) method for FTIR measures the reflectance spectrum of a sample placed upon the surface of a high refractive index optical crystal. The ATR mode of FTIR measurement allows the spectra of solids to be measured without dilution in KBr, and for materials to be measured without grinding or other alterations. It also enables FTIR spectra to be collected in the presence of water. Water is an extremely strong infrared absorber, and traditional sampling methods require drying to remove interference from H₂O. The ATR technique circumvents this limitation by directing the infrared beam through a long crystal. The beam is redirected through the crystal at an angle and bounces multiple times internally and then exits to the detector. The infrared beam produces an evanescent wave on the surface of the crystal, and hydrated samples in close contact with the crystal can be analyzed by comparing the reflectance of the sample with that of the bare crystal. A typical experimental configuration for ATR-mode experiments is shown in Fig. 3.

The ATR technique presents a substantial deviation from a transmission-mode experiment, therefore, experimental complications that affect the adherence of ATR data to the Beer-Lambert law are to be expected. For example, the effective path length of the beam is required for quantitative research and is related to the number of reflections through the crystal and the depth of penetration into the sample. The number of reflections is related to the ATR crystal's physical properties such as angle of incidence of the crystal, and the crystal's physical length and thickness. The depth of penetration into the sample is also related to the physical dimensions of the crystal, but is also a function of both the crystal and the sample's refractive index and the wavelength of light that is passed through the crystal. The ATR crystals may have 30°, 45°, or 60° effective angles of incidence, and may be made of a variety of materials. The most common and widely used material for ATR crystals is ZnSe (zinc selenide), but diamond, amorphous material transmitting IR (AMTIR), germanium, and silicon are also available. Different crystal materials may be preferred due to their refractive index, their useful spectral range, or their chemical sensitivity.

Modern ATR accessories typically feature a 1–3 reflection diamond coated ZnSe crystal for better chemical and physical resistance and ease of maintenance; the decreased surface contact area is compensated for by slightly more efficient reflection of IR light such that a 1-reflection diamond ATR signal is often 30–40% as strong as a traditional horizontal ATR crystal. In addition to ease of use improvements for the diamond ATR designs, fewer reflections mean that water does not fully absorb the infrared light in single reflection experiments and so the spectral range of study is expanded and vibrations of the water of hydration and surface functional groups can often be resolved in aqueous experiments.

The fact that sample penetration depth changes with wavelength presents a serious problem in attempting quantitative experiments with the ATR method. For this reason, ATR data are properly reported as percentage reflectance (%R) rather than percentage transmittance (%T), as the intensity of light transmitted is not constant throughout the spectrum with ATR, but instead is a function of wavelength. Fortunately, a mathematical correction can be made to ATR data that accounts for the wavelength dependence on penetration depth. This correction is typically available in the instrument's data-collection software.

With the ATR technique, it is possible to analyze a wide range of samples. Solids can be pressed into contact with the ATR crystal, while liquid samples and hydrated suspensions can be placed into a sample holder that has a trough with a volume of a few milliliters. This flexibility in sampling has made it possible to conduct adsorption studies of organic acids and oxyanions in situ with FTIR. The ability to monitor the mechanism of adsorption on mineral surfaces is the primary application of ATR-FTIR in environmental science (Suarez et al., 1998).

The primary advantage of the ATR method for environmental science research is that it allows environmental samples to be analyzed with normal amounts of water present and at ambient pressures. The results from ATR are therefore much more representative of chemistry in natural systems. However, ATR experiments are more difficult to compare with traditional transmission studies, difficult to conduct reliably in a quantitative manner, and the experimental procedure is more time-consuming than other methods.

Example ATR experiments

The most common uses for ATR-FTIR in the environmental sciences are in adsorption experiments between an IR-active adsorbate and a large surface area mineral adsorbent. Two experimental approaches are typically utilized in adsorption studies: analysis of reacted suspensions of soil solids, and analysis of adsorption on to solids deposited on to the ATR crystal. Both experimental approaches have merits and drawbacks. It is faster and easier to conduct macroscopic adsorption experiments in the laboratory and then use ATR-FTIR spectroscopy to analyze representative samples than it is to conduct all experiments in situ with deposited solids. This also provides the opportunity to determine the exact surface loading and reaction conditions of the sample prior to analysis. However, using wet pastes or slurries presents some experimental difficulties. Specifically, to obtain a spectrum of the adsorbed species, one must separate the solid from the solution by filtration, resuspend the solid in the supernatant at a constant solid-to-solution ratio for all samples, and then measure a spectrum of the supernatant, the unreacted solid, and the reacted solid. By subtracting both the supernatant and the unreacted solid spectra from the reacted spectrum, the result is the spectrum of the adsorbed species.

In contrast, the deposition method places a thin coating of a mineral on to the ATR crystal that is constant throughout the experiment. A reference spectrum of the ATR crystal, the mineral deposit, background electrolyte, and water is measured. Then, the reactant is added to the solution at a low (micromolar) concentration. The reactant is concentrated at the mineral-crystal interface so that adsorbed species are above detection limits. Since the solid concentration at the surface is constant and the solution-phase reactant is not detected, a high-quality spectrum of the absorbed ion can be obtained. With improved spectral quality, results from deposition studies are typically much easier to fit and interpret. The use of a flow cell and separate controlled environment reaction vessel also enables adsorption (and desorption) experiments to be carried out in real time. This can produce adsorption isotherms by systematically adjusting reactant concentration (see Fig. 4), pH envelopes or edges by adjusting reaction pH, or kinetics (Fig. 5) by collecting measurements repeatedly and rapidly as a function of time.

In addition to equilibrium-based adsorption studies detailed above, improvements in rates of data acquisition and FTIR instrumental capabilities make performing adsorption kinetics experiments at a time resolution of seconds possible (Parikh et al., 2008). Fig. 5 details a representative kinetics ATR-FTIR study of sulfate adsorption on FeOOH (ferric oxyhydroxide) at pH 4.0. This experimental approach makes it possible to follow reaction mechanisms of many soil reactions in situ and extract both rate parameters and complexation information simultaneously. For more details of experimental methodology, see Schmidt et al. (2020).

Fig. 6 A representative ATR-FTIR spectrum of whole soil showing the fitted Gaussian peaks representing major C functional groups within the wavenumber range of 1800–900 cm^{-1} . Peaks are identified as follows: 1–917 cm^{-1} ; 2–986 cm^{-1} ; 3–1037 cm^{-1} ; 4–1103 cm^{-1} ; 5–1162 cm^{-1} ; 6–1370 cm^{-1} ; 7–1434 cm^{-1} ; 8–1509 cm^{-1} ; 9–1584 cm^{-1} ; 10–1644 cm^{-1} .

The ATR analysis of soil organic matter (SOM)

The ATR-FTIR spectra of soil samples can be used to characterize the major absorbance bands representing different functional groups in SOM. Due to interference from clay mineral and carbonate vibrations, the wavenumber range of 1800–900 cm^{-1} is often chosen for analysis of C functional groups. Because there is strong overlap among the bands of organic functional groups within this wavenumber range, the individual bands must be resolved by spectral deconvolution into individual bands by Gaussian peak fitting. A typical soil spectrum with functional group peaks fitted is shown in Fig. 6.

Polysaccharides, alcohols, and ether C appears at 1000–1160 cm^{-1} (peaks 3–5); aliphatic and aromatic C bands appear at 1420–30 and 1510 cm^{-1} (peaks 7 and 8); and aromatic and conjugated carboxylic functional groups appear at 1580–1650 cm^{-1} (peaks 9 and 10) (Dhillon et al., 2017). When many soil spectra are analyzed and compared, the results are useful in studying trends and changes in the relative amounts of SOM functional groups, such as in the PCA (principal component analysis) in Fig. 6.

Conclusions

Fourier Transform Infrared spectroscopy (FTIR) has been used for decades as a method to identify and quantify minerals in soil samples. More recently, improvements in sampling methods such as Attenuated Total Reflectance have extended the utility of FTIR to samples with water present. This makes it far more useful for the analysis of adsorption samples either as slurries or via thin film studies in situ. Fourier Transform Infrared spectroscopy is also increasingly used for characterizing soil organic matter functionality. As advances in instrument capabilities reduce signal to noise and increase throughput, and multivariate data analysis approaches such as MCR and PCA are feasible, it is expected that FTIR will increasingly be integrated with ecosystem and field scale studies as well as kinetic experiments.

Abstract

Electron paramagnetic resonance (EPR) spectroscopy is a nondestructive, noninvasive, highly sensitive and accurate analytical technique applicable to chemical species that possess one or more unpaired electrons. The first part of this chapter summarizes the basic principles, instrumentation and methodology of EPR spectroscopy. In the second part, the main applications of EPR to the study of indigenous and transient organic free radicals present in soil humic substances and their interactions with organic chemicals, together with paramagnetic transition metal ions in soil constituents, are described. The chapter ends with a brief overview of spin derivatization approaches and conclusion and perspectives.

Key points

- Electron paramagnetic resonance spectroscopy (EPR) provides basic principles of the resonance phenomenon, instrumentation and methodology, sample preparation and determination and interpretation of spectral parameters.
- Application of EPR to whole soil samples.
- Application of EPR to the study of organic free radicals in soil humic substances, interpretation and factors affecting EPR spectra and parameters, structural implications.
- EPR to study the interactions of humic free radicals with organic chemicals and metal ions.

- Application of EPR to the study of paramagnetic metal ions in soil organic and mineral constituents, EPR spectra and parameters, ferric iron, divalent copper, vanadyl ion, divalent manganese.
- Spin derivatization, spin-labeling, spin-trapping, metal spin probes, complexation chemistry of humic substances, ion exchange on layer silicates, chemisorption on mineral surfaces, thermodynamic constants from EPR parameters.

Nomenclature

EPR	Electron Paramagnetic Resonance
ESR	Electron Spin Resonance
ENDOR	Electron Nuclear Double Resonance
ESEEM	Electron Spin Echo Envelope Modulation
NMR	Nuclear Magnetic Resonance
HS	Humic Substances
HA	Humic Acid
FA	Fulvic Acid
DPPH	<i>N,N</i> -diphenylpicrylhydrazyl
Q	Quinone
H ₂ Q	Hydroquinone
HQ [•]	Semiquinone radical
Q ^{•-}	Semiquinone radical anion
5-SASL	Stearic Acid Spin-Label with nitroxide free radical in position 5 of the hydrocarbon chain
DMPO	5,5-dimethylpyrroline 1-oxide
PBN	phenyl- <i>N</i> - <i>t</i> -butylnitrone
RT	Room Temperature
DC	Direct Current
H, H ₀	Strength of the static magnetic field
ΔH	Width of the resonance line, or linewidth
E	Energy for the unpaired electron
ΔE	Absorption of energy by the electron
h	Planck's constant
μ _z	Electron magnetic moment
β	Electron Bohr magneton
M _z	Electron spin angular momentum
S	Electron spin
ν ₀	Frequency of the alternating magnetic field
g	Electronic splitting factor, or g-value, or g-tensor
g _{xx} , g _{yy} , and g _{zz}	Components of the g-tensor along the axes x, y, z
g _{iso} or g ₀	Isotropic g-factor
g	Component of the g-tensor parallel to the symmetry axis
g _⊥	Component of the g-tensor perpendicular to the z-axis
A	Hyperfine coupling constant
I	Nuclear spin
T	Tesla
q _u	Weight of the sample
K _c	Weighted average equilibrium constant

Introduction

Electron paramagnetic resonance (EPR) spectroscopy, otherwise known as electron spin resonance (ESR) spectroscopy, is a nondestructive, noninvasive, highly sensitive and accurate analytical technique that can detect and characterize paramagnetic chemical species possessing unpaired electrons (among several others, [Weil et al., 1994](#); [McBride, 1986](#)). Soil species able to produce EPR spectra include organic free radical moieties in humic substances (HS) and organic- and mineral-associated paramagnetic metal ions ([Senesi and Steelink, 1989](#); [Senesi and Chen, 1989](#); [Senesi, 1990a, 1990b, 1996](#); [Cheshire and Senesi, 1998](#); [Senesi and Loffredo, 2005, 2008](#)). Further, EPR labeling, trapping and metal probing methods are used to study the dynamics of macromolecules in soil solution, HS complexation chemistry, and ion sorption on mineral surfaces (among several others, [Berliner, 1976](#)).

Basic principles

The resonance phenomenon

The basic physical phenomenon underlying EPR spectroscopy is referred to as the Zeeman effect, which consists of the interaction between the magnetic moment of an unpaired electron and an external magnetic field that produces the splitting of the energy levels of the unpaired electron. If a static magnetic field of strength H is applied in the z -direction, i.e., parallel to the z -axis, the Zeeman interaction leads to an energy, E , for an unpaired electron given by:

$$E = -\mu_z H = -g \beta H M_z \quad (1)$$

where μ_z is the electron magnetic moment in the direction of the conventional z -axis; g is a dimensionless constant called the spectroscopic splitting factor or g -value; β is the electron Bohr magneton; and M_z is the component of the electron spin angular momentum in the direction of the applied magnetic field H (z -axis). The values that M_z may assume are $+1/2$ or $-1/2$ depending on the alignment of the electron spin, S , either parallel (high energy) or antiparallel (low energy) to the magnetic field direction. Thus, two energy levels exist with an energy difference that increases linearly with the magnitude of H (Fig. 1).

In a sample containing unpaired electrons in thermodynamic equilibrium in a magnetic field of value H_0 , a population difference exists between the two energy levels with an excess population in the lower level. If an incident electromagnetic radiation is supplied to the sample, e.g., by applying an alternating magnetic field of frequency ν_0 perpendicular to the static magnetic field H_0 , an absorption of energy, ΔE , occurs provided that ν_0 satisfies the following equation:

$$h\nu_0 = \Delta E = g \beta H_0 \quad (2)$$

where h is the Planck's constant. This is known as the 'resonance condition'. The measurement of this energy absorption, recorded as its first derivative, is the EPR signal (Fig. 1), i.e., the basis of EPR spectroscopy.

Spectral parameters

The position and shape of the EPR signal depend on the environmental conditions in the vicinity of the electron, which may result in spectral patterns more complicated (Fig. 1b) than the single-line spectrum (Fig. 1a). The most important effects that influence the position and pattern of the EPR spectrum are the 'electron Zeeman', 'nuclear hyperfine', 'ligand superhyperfine', and 'nuclear quadrupole' interactions. These effects are related to spectral parameters that include the g -factor and nuclear hyperfine and superhyperfine coupling constants.

For a given magnetic field and a particular microwave frequency, the 'electron Zeeman' effect shifts the resonance position of the free electron from a value of $g = 2.00232$ to one that depends on the molecular properties of the paramagnetic species (Eq. 2). The g -value of organic free radicals is generally close to 2.00, and does not distinguish well between different radicals, whereas for paramagnetic metal ions g is often typical of a particular ion and its valence state. For most paramagnetic ions g is anisotropic, i.e., dependent on the orientation of the molecule relative to the external magnetic field, and is completely described by the three components, g_{xx} , g_{yy} , and g_{zz} , along the three axes x , y , z that are generally coincident with molecular symmetry axes. These three components differ from each other ($g_{xx} \neq g_{yy} \neq g_{zz}$) for paramagnetic species that have no principal axis of symmetry, whereas a

Fig. 1 Effect of an applied magnetic field, H , on the energy levels (E) of the two spin states of an electron ($M_z = \pm 1/2$). EPR transition(s) at $\nu_0 = g \beta H_0/h$, actual absorption curve, and experimental first-derivative EPR spectrum for the cases of no nuclear interaction (a) and interaction with a nucleus having $I = 3/2$ (b), e.g., Cu^{2+} . The nuclear hyperfine splitting is given by $A/g\beta$.

single isotropic g -factor, g_{iso} or $g_0 = 1/3$ ($g_{xx} = g_{yy} = g_{zz}$) is exhibited by octahedral, tetrahedral, or cubic symmetries. Species with 'axial symmetry', such as Cu^{2+} (copper) and V^{4+} (vanadium), have one principal or a threefold axis of symmetry, conventionally the z -axis, and equivalent x - and y -axes. These species feature so-called 'rigid-limit' spectra and have two g -values, usually labeled $g_{\parallel}$ ($= g_{zz}$, the g -value parallel to the symmetry axis, or z -axis), and $g_{\perp}$ ($= g_{xx} = g_{yy}$, the g -value perpendicular to the z -axis in the x,y -plane). The g -values can provide information on the nature of the paramagnetic species and the symmetry of the metal ion in the sample matrix.

The 'hyperfine splitting or structure' arises from the 'nuclear hyperfine' interaction of the unpaired electron with its nucleus if it features a nonzero spin ($I \neq 0$), such as Cu ($I = 3/2$), Mn (manganese, $I = 5/2$) or V ($I = 7/2$), and is independent of the applied field, H_0 . Permanent local fields arising from magnetic nuclei split each electron spin level into $2I + 1$ components, which results in a set of $2I + 1$ equally spaced hyperfine-structure lines replacing the single line resonance in the EPR spectrum. For example, four lines appear for Cu (Fig. 1b), six for Mn, and eight for V. The hyperfine splitting is generally approximated by $A/g\beta$, where A is the magnitude of the nuclear hyperfine interaction, the so-called 'hyperfine coupling constant'. The parameter A , like g , may also exhibit an orientation-dependence (i.e., anisotropy), and may provide useful information on the nature and molecular symmetry of paramagnetic species possessing magnetic nuclei.

The 'superhyperfine splitting or structure' arises when an interaction occurs between the unpaired electron and ligand nuclei having nonzero nuclear spin in paramagnetic metal-ligand complexes. The most common nucleus giving rise to superhyperfine structures in EPR spectra is ^{14}N (nitrogen), which has a nuclear spin, $I = 1$. Thus, each hyperfine line is split into three approximately equally spaced components of equal intensity. Very complex spectra are obtained, however, when more than one N-ligand, especially if not equivalent, is involved in metal complexation.

The 'nuclear quadrupole' interaction arises from the nuclear quadrupole moment (for example, of the Mn nucleus, $I = 5/2$) and the electric field gradient. The interaction, besides modifying the hyperfine splitting, also 'mixes' the hyperfine levels, so that 'forbidden' transitions can occur. In general, quadrupole effects are very small and rarely observed in powder and frozen solution spectra.

Instrumentation and methodology

The instrument and the experiment

The basic components of a typical EPR spectrometer operating in the X-band (microwave) frequency region of the electromagnetic spectrum are (Fig. 2): (a) an electromagnet supplying a static, or direct current (DC), continuous magnetic field that can be varied in strength, usually in the range 0–1 T (1 T (T) = 10^4 gauss); (b) the source of microwaves, usually a vacuum tube oscillator named 'klystron' that provides a monochromatic coherent source of electromagnetic radiation with a frequency typically around 9.5 GHz that is held constant to within 1 part in 10^6 ; (c) a resonant or 'microwave' cavity, which is a hollow-conducting box generally cuboid where the sample is placed and irradiated; (d) a waveguide that couples the klystron to the resonant cavity that is locked electronically to the resonance frequency; (e) a circulator incorporated between the klystron and the cavity, which ensures optimum transfer of the microwave power from the klystron to the cavity and from the cavity to the detector; (f) a small iris diaphragm that interfaces the cavity to the waveguide, and whose effective diameter can be varied until all the incident microwaves are absorbed by the cavity so that it is said to be 'critically coupled'; (g) a magnetic field modulator that increases the intensity of the reflected

Fig. 2 Block diagram of a typical X-band EPR spectrometer.

microwave at low frequency (usually 100 KHz) by superimposing upon the external magnetic field H_0 a second magnetic field of a few tens of milliT; and (h) a phase-sensitive detector locked to the magnetic field modulation frequency.

In the practical EPR experiment, the microwave frequency is usually fixed and the applied external magnetic field is continuously swept until the resonance condition (Eq. 2) is met. Most EPR spectrometers enable repetitive sweeping of the magnetic field through the resonance, and employ a computer to average transients, thus improving sensitivity. The output of the detector-amplifier system, that is, the EPR spectrum, is displayed as the first derivative of the absorption peak, and recorded on a chart recorder as a function of the applied external magnetic field, H (Fig. 1). Occasionally, the second derivative is plotted to improve the resolution of lines that are close together.

Sample preparation

The EPR technique can analyze samples in any form, that is, liquid, solid powder, amorphous polymer, frozen glass, or single crystal. In general, solid powders are packed into an EPR tube with an inside diameter of a few millimeters. Aqueous solutions or suspensions are placed in capillary tubes or specially designed flat cells to reduce dielectric absorption of microwave radiation by water molecules. Tubes and cells are made of very pure quartz with no defects, which gives no EPR signal and has a very small dielectric loss. Clay films also can be used by mounting them on flat quartz 'tissue cells'.

Removal of paramagnetic O_2 (oxygen) molecules that can broaden EPR spectra by dipole-dipole interaction is sometimes required before EPR analysis. If the concentration of paramagnetic species in a sample is too large, the sample must be diluted magnetically in a diamagnetic matrix to minimize spin-spin coupling that may broaden the spectrum.

Sensitivity and resolution

The sensitivity of the technique depends primarily upon the number of spins present in the sample. Typically, a conventional X-band spectrometer can detect 10^{15} to 10^{16} spins, which implies a sensitivity of 10^{-7} to 10^{-8} mol. The sample must be placed correctly in the cavity that generally has a detection region about 2-cm high, with the greatest sensitivity at its center. Sensitivity is generally improved by setting the modulation amplitude at larger values that, however, should not exceed a fraction of the peak-to-peak resonance linewidth, otherwise distortion of the spectral line shape can occur. According to Curie's law, maximum sensitivity for paramagnetic species is attained at the smallest possible sample temperature. Although organic free radical species can generally be measured easily at room temperature (RT), for most paramagnetic metal ions cooling at liquid N_2 (boiling point = 77 K) or liquid He (boiling point = 4.2 K) temperature is often required. The extremely large dielectric loss of water at microwave frequencies prevents analysis at RT with aqueous systems, and requires EPR measurements to be made at liquid N_2 or liquid He temperature on frozen aqueous solutions. However, large metal-organic molecules cannot tumble rapidly in solution, thus the EPR spectrum at RT is often similar to that observed for powders or frozen solutions.

The major limitation of an EPR experiment is the resolution of the signal linewidths that may overlap to such an extent that information is lost. The resonance linewidth is affected by two mechanisms, namely, homogeneous and inhomogeneous broadening. The most important homogeneous broadening effects are: (a) 'spin-lattice relaxation' by which an electron at a higher energy level returns to the ground state by losing energy to its environment (i.e., the 'lattice'), either in a short time, thus producing linewidth broadening, or over a long time, which results in narrower linewidths; and (b) 'microwave-power saturation' that may arise if a sufficiently large microwave power is applied that tends to equalize the electron populations of the two levels, thus decreasing signal intensity and increasing linewidth. In the absence of saturation, the EPR signal intensity should increase as the square root of the microwave power. Inhomogeneous broadening arises from non-uniformities in the magnetic field throughout the sample resulting from other neighboring paramagnetic species or from neighboring magnetic nuclei, or from dipolar interactions between unlike spins. These effects, often referred to as 'spin-spin interactions', are random in direction and result in the merging of individual resonant lines or spin packets into a single overall line or envelope, with loss of line resolution and related information.

Two techniques are potentially useful to overcome the limitation related to linewidth resolution: (i) electron nuclear double magnetic resonance (ENDOR) spectroscopy, that is a combination of EPR and nuclear magnetic resonance (NMR) techniques; and (ii) electron spin echo envelope modulation (ESEEM) spectroscopy, that is a time-domain electron magnetic resonance technique (Kevan and Kispert, 1976; Kevan and Schwartz, 1979). Both techniques can extend the resolution of hyperfine and superhyperfine contributions to inhomogeneously broadened single-line EPR spectra.

Determination and interpretation of spectral parameters

Once the EPR spectrum has been measured, values of spectral parameters can be determined accurately and rigorously by comparing the experimental spectrum to a computer-simulated spectrum for the species being studied, which is analyzed using trial parameters and expressions for the magnetic fields at which transitions occur. Then, the procedure is repeated until satisfactory agreement is found between the two spectra. In practice, elaborate computer simulation may be avoided by the relatively simple, even though not rigorous, computation of spectral parameters directly from the experimental EPR spectrum and from spectrometer measurement settings using the equations described in detail later.

Once the EPR parameters have been obtained, they can be related to the nature of paramagnetic species, metal oxidation state, and type and site symmetry of metal binding by using rigorous physicochemical approaches and complex mathematical tools. This procedure can be avoided by empirical comparison and correlation of experimentally obtained EPR spectral parameters with EPR data available on similar model, synthetic, or natural systems, which can provide the information of chemical and structural interest to the soil scientist.

Whole soil

The EPR spectra of whole soil samples commonly show a very broad and intense ferromagnetic resonance peak centered at approximately $g = 2.00$, which can be attributed to strongly magnetic materials consisting of randomly oriented crystals and or polycrystalline powdered particles of different shapes and random orientation, such as iron oxihydroxides and minerals rich in Mn, Ti (titanium) and other transition metals (Senesi, 1996). High porosity and crystal defects and or impurities can further increase EPR signal linewidth. As a result of these effects, EPR of a whole soil sample provides only very limited chemical and structural information, thus soil components, i.e., HS and their most important fractions, humic acid (HA) and fulvic acid (FA), metal-HS complexes, clay minerals and metal-clay associations must be isolated from the sample and studied separately.

Organic free radicals in soil humic substances

The EPR spectra and parameters

Humic substances are the most abundant, and most chemically and biologically active fraction of the nonliving organic matter in soil, whose macromolecules typically contain indigenous free radical moieties. The EPR spectrum of HS free radicals is usually obtained at RT on solid or water-dissolved samples of unfractionated HS, and HA and FA fractions and subfractions (Cheshire and Senesi, 1998; Senesi, 1996). The magnetic field is swept over a relatively narrow scan range (generally 5–10 mT) through the field at which the free electron resonates until the resonance condition is met, which generally occurs at a field of about 340 mT and corresponds to a g -value close to that of the free electron. Typical spectrometer settings and operating conditions used in the measurement of EPR spectra of HS free radicals are: microwave frequency close to 9.5 GHz; microwave attenuation, 13 dB, corresponding to a microwave power of about 10 mW, at which the signal is generally least saturated; and modulation amplitude, 0.63 mT (Cheshire and Senesi, 1998; Senesi, 1996). A typical EPR spectrum of HA and FA free radicals features a single-line resonance, devoid of any structure (Fig. 3a), while a partially resolved hyperfine structure is rarely observed (Atherton et al., 1967) (Fig. 3b).

Traditionally three spectral parameters of importance to characterize the nature, origin, and properties of HS free radicals can be derived from EPR spectra; they are the g -value, the width of the absorption line, i.e., the linewidth, and, rarely, the hyperfine structure (Cheshire and Senesi, 1998; Senesi and Steelink, 1989). The g -value can be accurately approximated from the magnitude of the magnetic field at which the resonance occurs for the sample and for a standard of known g -value, usually *N,N*-diphenylpicrylhydrazyl (DPPH) diluted in powdered KCl ($g_{\text{DPPH}} = 2.0036$). A small amount of the standard material in a capillary tube can be taped to the sample tube and its signal used as a field 'marker.' Since ν_0 is identical for both, the g -values of the sample and standard are readily calculated from the ratio of field positions using the relationship derived from Eq. (2) (Cheshire and Senesi, 1998; Senesi, 1996):

$$g_u = g_k H_k / H_u \quad (3)$$

where u (unknown) and k (known) refer to the sample and standard, respectively, and H_k can be calculated from Eq. (2) using ν_0 and g_k . The width of the resonance line, or linewidth, ΔH , is generally measured in Tesla or in gauss (1 gauss = 10^{-4} T), as the

Fig. 3 Typical single-line EPR spectrum of organic free radicals in soil humic acids and fulvic acids (a) (Reproduced with permission from Senesi N (1996) Electron spin (or paramagnetic) resonance spectroscopy. In Sparks DL (ed.) *Methods of Soil Analysis. Part 3. Chemical Methods*, Book Series No. 5, pp. 323–356, Madison, WI: Soil Sci. Soc. of America and American Soc. of Agronomy), and four-line EPR spectrum observed for some acid-boiled humic acids (b) (Reproduced with permission from Atherton NM, Cranwell PA, Floyd AJ and Haworth RD (1967) Humic acid I. ESR spectra of humic acid. *Tetrahedron* **23**: 1653–1667).

peak-to-peak separation of the first derivative EPR signal. The hyperfine splitting is measured as the separation (in gauss or in Tesla) between the hyperfine lines.

The concentration of unpaired electrons, i.e., of organic free radicals in HS can be determined by comparing its signal area with that of a standard char containing a known content of paramagnetic centers, e.g., the 'strong pitch' supplied by the manufacturer, or DPPH (Senesi, 1996; 1998). A double integration of the first derivative curves should be performed to obtain the corresponding areas rigorously. The line shape of the sample and standard are generally of the Lorentzian type, therefore, the double integration can be avoided by simply calculating each area as the product of the height (h) and square of the width (w) of the first derivative signal. If the sample undergoes hyperfine splitting, the area under the hyperfine lines must be summed to obtain the total area to be considered. The spin concentration, expressed in spins g^{-1} , can then be calculated by:

$$(\text{spin } g^{-1})_u = \left[(\text{spin } g^{-1})_k (hw^2)_u (\text{gain})_k \right] / \left[(hw^2)_k (\text{gain})_u q_u \right] \quad (4)$$

where u and k are as above Eq. (3), gain is the signal amplifier gain used and q_u is the weight (in grams, moisture and ash free) of the sample.

This procedure requires that the sample and standard are measured in an identical environment, i.e., the same matrix, geometry, volume, temperature, and spectrometer settings, therefore, either a double cavity instrument or concentric sample tubes should be used. More often, however, separate tubes for the sample and standard are used, placing them alternately in exactly the same position in the resonant cavity.

Interpretation of EPR parameters

The g -values commonly measured for organic free radicals in soil HAs and FAs range between 2.0030 and 2.0050, which are consistent with indigenous semiquinone radical moieties conjugated to aromatic rings (e.g., $g = 2.0041$ for 9,10-anthraquinone), although a contribution from methoxybenzene radicals (g -values range, 2.0035–2.0040) and N- or S-associated radicals ($g = 2.0031$ –2.0037) cannot be excluded (Senesi and Steelink, 1989; Cheshire and Senesi, 1998; Senesi, 1990a,b;).

The linewidths of the EPR signal of HA and FA free radicals generally range between 3.5 and 7.5×10^{-4} T for solid samples and between 2.0 and 3.0×10^{-4} T for the corresponding water solutions (Senesi, 1996). The EPR linewidths do not show any particular dependence on the nature and origin of FAs and HAs, but they are generally slightly greater for FA than for HA from the same source. Factors affecting EPR signal linewidth are free radical concentration and aggregation state of the sample, interactions with solvent and/or metal ions, power-saturation effects, and temperature.

The EPR spectra of HA and FA free radicals rarely show a hyperfine structure. For example, some acid-boiled HAs feature a four-line hyperfine structure (Atherton et al., 1967) (Fig. 3b) attributed to interaction of the unpaired electron with two nonequivalent H (hydrogen) nuclei, whereas an oxidized soil FA exhibits a three-line spectrum ascribed to the interaction of the unpaired electron of a semiquinone O atom with two adjacent equivalent H nuclei (Senesi et al., 1977a).

The concentration of organic free radicals in soil HAs and FAs depends on their nature and origin, and generally ranges between 10^{16} and 10^{18} spins g^{-1} (Senesi and Steelink, 1989). The FAs usually show one-third to one-fifth of the spin content of HAs from the same source. The spin concentration of FAs measured in solution at neutral and alkaline pHs is always greater than that measured in the solid state. Several factors affect the spin content measurement, including power saturation effects, the presence of pronounced shoulders associated with a broad signal, and, in the case of solution samples, the solvent, pH, and time (Senesi and Steelink, 1989; Senesi, 1990a, 1990b; Senesi, 1996). Caution should be used in evaluating and comparing the spin contents of HS. Reasonable reliability and comparability can be expected in the evaluation of changes in spin concentrations that occur in a certain sample subjected to differences in various physical and chemical conditions.

Factors affecting EPR parameters of humic substances

Changes of concentration, g -value and linewidth of free radicals in HS subjected to differences in pH, ionic strength, state of aggregation, hydrolysis, alkylation, redox potential, irradiation, temperature, and humidity, can provide valuable insight into their molecular features (Senesi and Steelink, 1989; Cheshire and Senesi, 1998; Senesi, 1990a,b, 1996).

Increase of pH, chemical reduction, acid hydrolysis, or visible- and ultraviolet (UV)-light irradiation enhances the free radical concentration of HS, while leaving the g -value and signal linewidth almost unaltered (Senesi, 1990a, 1990b, 1996; Cheshire and Senesi, 1998; Senesi and Schnitzer, 1977; Steelink and Tollin, 1967; Riffaldi and Schnitzer, 1972). In all cases, except acid hydrolysis, the increase in spin content is not sustained over time, i.e., it returns gradually, and almost reversibly, to a value similar to that before the treatment. These results suggest that short-lived, 'transient' free radicals chemically similar to stable native radicals are produced in HS with any of the mentioned treatments.

An increase in temperature to 450°C or exposure to high-energy irradiation (gamma rays) causes a marked increase in spin content, broadening of linewidths, and decrease of g -value in solid HAs (Senesi, 1990a, 1990b; Senesi et al., 1977b; Schnitzer and Skinner, 1969). These changes, which are accompanied by the loss of O and increase in C (carbon) content, can be ascribed to homolytic bond-cleavage and subsequent delocalization and stabilization of newly-produced free electrons from semiquinonic O atoms to aromatic C atoms.

Chemical or electrochemical oxidation generally produces a time- and pH-dependent decrease of the free radical content of water-dissolved HAs and FAs, which is reversed by a subsequent reduction treatment (Senesi, 1990a, 1990b). A decrease in spin content is also observed with an increase of neutral electrolyte concentration in FA and HA solutions at a pH close to neutrality (Senesi and Schnitzer, 1977). However, no changes in g-values or linewidths are observed with any of these treatments. A decrease of both organic free radical concentration and EPR signal linewidth is observed with increasing humidity of solid HA samples, which is almost reversible upon re-drying of the samples. Contrasting results have been obtained for the effect of methylation on the free radical content of HS, i.e., it decreases dramatically for the HAs and FAs of podzolic soil, whereas it increases for several other soil HAs and FAs (Senesi and Steelink, 1989; Steelink and Tollin, 1967; Schnitzer and Skinner, 1969).

Structural implications

The free radical concentration is correlated to other compositional and structural parameters of HS, either positively, e.g., to the E_4/E_6 ratio (ratio of absorbance at 465 and 665 nm), absorbance at 465 nm, atomic C/H and O/C ratios, O percentage, phenolic OH content, and aromaticity, or negatively, e.g., to H percentage and aliphaticity (Senesi, 1990a, 1990b; Steelink and Tollin, 1967; Schnitzer and Skinner, 1969; Chen et al., 1977). These results suggest that the free radical content is directly related to the dark color, aromatic or aliphatic character, molecular complexity and particle size of HS. A strong correlation also exists between the free radical concentration and degree of humification of HS in peat soils and in organically amended soils (Cheshire and Senesi, 1998).

Accumulated evidence from EPR (Senesi and Steelink, 1989; Cheshire and Senesi, 1998; Senesi, 1990a,b) strongly supports an indigenous quinone (Q)-hydroquinone (H_2Q) system as that principally responsible for the generation and stabilization of semiquinone radicals ($HQ^\bullet$) and radical anions ($Q^{\bullet-}$) in HS macromolecules, which is based on the simple electron donor-acceptor (or charge-transfer) reversible mechanism:

The large decrease in spin content observed in podzolic HAs and FAs from the selective blocking of phenolic OH groups by methylation confirms these groups as the most important electron donors responsible for the formation and existence of organic free radicals in HS (Schnitzer and Skinner, 1969). A quinone content of 0.5 mmole g^{-1} , typical of most HAs, would theoretically yield up to 6×10^{20} spins g^{-1} of the semiquinone anion at alkaline pH and in the presence of a donor group such as hydroquinone. This effect can increase the amount of stable free radicals in HS from two to five orders of magnitude, with relevant implications in their chemical and biochemical reactivity. Further, semiquinone radicals can be generated by reduction or photoirradiation of quinones in solution in the presence of electron donors (Senesi, 1990a, 1990b).

Interactions of humic free radicals with organic chemicals and metal ions

The EPR technique can be applied usefully for evaluating the role of organic free radicals in the interaction of HS with organic chemicals, such as pesticides (Cheshire and Senesi, 1998; Senesi, 1990a,b). For example, the increase in free radical concentration measured in the interaction products between HAs and s-triazine or substituted urea herbicides provides evidence of the occurrence of an electron donor-acceptor mechanism, with formation of charge-transfer complexes (Senesi and Chen, 1989). In contrast, the products of interaction of chlorophenoxyalkanoic herbicides with HA show a considerable decrease in free radical concentration which suggests the occurrence of homolytic cross-coupling reactions between HA free radicals and free radical intermediates generated in the preliminary chemical, photochemical, and/or biological degradation of the herbicide (Senesi and Chen, 1989).

The EPR spectroscopy can also be used to study the effect of some metal ions on HS free radicals (Cheshire and Senesi, 1998). In general, the addition of diamagnetic metal ions such as Na^+ (sodium), Zn^{2+} (zinc) and Al^{3+} (aluminium) to HA or FA solutions does not affect their free radical content, whereas addition of paramagnetic metal ions such as Fe^{3+} (iron), Cu^{2+} , Mn^{2+} , VO^{2+} (vanadium oxide), Ni^{2+} (nickel) and Co^{2+} (cobalt) causes a marked decrease of HS free radical content as a function of the metal species and HS origin (Cheshire and Senesi, 1998). In studies of podzolization processes, EPR data suggest that recently formed, low-molecular weight HS cannot undergo further polymerization because their free radicals combine with Fe^{3+} and move to the Bh horizon (Cheshire and Senesi, 1998). In another study, EPR spectroscopy revealed the formation of semiquinone radicals by single electron transfers occurring at goethite and manganese oxide surfaces during the oxidation of hydroquinone (Cheshire and Senesi, 1998). Further, EPR spectroscopy can be used to characterize the nature of HS formed by oxidative polymerization of phenolic and other organic compounds in the presence of natural clays, soils, soil oxides, and other metal ion catalysts (Cheshire and Senesi, 1998).

Paramagnetic transition metal ions in soil

The EPR technique can be successfully applied to study natural complexes of paramagnetic metal ions of importance in soil, such as Fe^{3+} , Cu^{2+} , Mn^{2+} , and V^{4+} , with HAs, FAs and plant litter, and structural paramagnetic metal ions, such as Fe^{3+} , in soil minerals (Senesi, 1990a, 1990b, 1992, 1996; Cheshire and Senesi, 1998; Senesi and Loffredo, 2005, 2008). In particular, EPR analysis can provide unique information on the identity and oxidation states of metal ions, metal binding site(s) including ligand types, coordination and symmetry, and stability of metal-organic complexes.

The EPR spectra and parameters

The EPR spectra of paramagnetic metals in soil organic and mineral constituents are usually obtained at either RT on powder samples or at liquid N₂ temperature (77 K) on powders or frozen (77 K) solution samples. The magnetic field is usually scanned tentatively at first over a wide range of strengths (from 0 T to 1 T), then an enlarged spectrum is recorded over a narrower field (0.2 T or 0.1 T) comprising the region where resonances appear to enable their detailed analysis and interpretation. Measurement conditions commonly employed are: microwave frequency, approximately 9.2 GHz (spectra at 77 K) or 9.8 GHz (spectra at RT); microwave attenuation, 13 dB (microwave power oscillates between 9.0 and 9.2 mW); and modulation amplitude, between 0.63 and 4 mT, according to the metal ion being measured (Senesi, 1992). Four examples of typical EPR spectra of metal-organic complexes that occur naturally in isolated soil organic fractions are shown in Figs. 4 and 5.

Three types of spectral parameters can be obtained from EPR spectra of metal-organic complexes: (i) the *g*-value(s) of the metal(s) in the sample; (ii) the hyperfine coupling constant(s), *A*, if the metal nucleus has a nonzero spin; and (iii) the ligand superhyperfine splitting(s), if the unpaired electron of the metal ion is delocalized onto magnetic nuclei of surrounding ligands. Resonance lines due to 'forbidden transitions' are rarely observed, e.g., for Mn²⁺ (Senesi, 1990a, 1990b, 1992, 1996; Cheshire and Senesi, 1998; Senesi and Loffredo, 2005, 2008).

The *g*-values and hyperfine and superhyperfine constants, *A*, can be calculated from experimental spectral data and the values of spectrometer settings used according to the standard equations (Senesi and Loffredo, 2005, 2008):

$$g = h \nu_0 / \beta H_0 = 0.714484 \nu_0 / H_0 \quad (6)$$

$$A \text{ (cm}^{-1}\text{)} = A \text{ (MHz)} / c = 2.80247 (a \text{ g}) / (c g_e) = 0.469766 \cdot 10^{-4} a \text{ g} \quad (7)$$

where ν_0 (MHz) is the microwave frequency at the resonance condition; H_0 is the value of the magnetic field at which the resonance is centered (on calibrated chart paper); g_e (=2.00232) is the *g*-value of the free electron calculated by Eq. (6); *a* is the hyperfine splitting measured as the peak-to-peak separation (in 10⁻⁴ T) between the hyperfine lines in the experimental spectrum; and *c* is the speed of light in a vacuum. Accuracy of the magnetic field calibration of chart paper should be checked using a suitable standard.

Ferric iron

The EPR spectra of HAs, FAs and decomposing litter layers generally exhibit an asymmetrical isotropic resonance line at about *g* = 4.2, which is consistent with high spin (five unpaired d-electrons) Fe³⁺ ions held in tetrahedral or octahedral sites of a low-symmetry (rhombic) ligand field possibly by carboxylic and/or phenolic hydroxyl groups (Fig. 4a) (Senesi, 1992; Senesi and Loffredo, 2005, 2008; Senesi et al., 1986; Senesi et al., 1991). This form of Fe exhibits considerable resistance to proton and metal exchange, and to chemical reduction, which suggests that Fe³⁺ is strongly bound and protected in inner-sphere complexes in HS.

A very broad signal near *g* = 2 is often exhibited by HS (Fig. 4a'), which possibly arises from extended spin-spin coupling of various neighboring Fe³⁺ ions (Senesi, 1992; Senesi and Loffredo, 2005, 2008; Senesi et al., 1986; Senesi et al., 1991). Iron in such

(Reproduced with permission from Senesi N (1996). Electron spin (or paramagnetic) resonance spectroscopy. In Sparks DL (ed.) *Methods of Soil Analysis. Part 3. Chemical Methods*, Book Series No. 5, pp. 323–356, Madison, WI: Soil Sci. Soc. of America and American Soc. of Agronomy).

Fig. 5 Same EPR spectra as in Fig. 4b, c, d, but recorded on an enlarged scan range (200 mT).

sites is easily reduced by chemical agents and easily extracted by complexing agents, suggesting that it is weakly bound on the external surfaces of HS. Two weak resonances near $g = 9$ and $g = 6$ are sometimes observed in EPR spectra of HS, which possibly arise, respectively, from Fe^{3+} at sites with near orthorhombic symmetry and from high-spin Fe^{3+} in largely distorted, axially symmetric crystal fields (Senesi et al., 1991).

An EPR signal at $g = 4.3$ can be observed in layer silicates such as kaolinites, vermiculites, micas and smectites, which have anisotropic and isotropic g -factors that possibly arise from structural octahedral $\text{FeO}_4(\text{OH})_2$ groups (McBride, 1986, 1989). Soil clays such as vermiculites and weathered phlogopite often exhibit strong ferrimagnetic resonance at $g = 2$ that can be attributed to ferrimagnetic clusters of structural Fe^{3+} and/or ferric oxides and tends to obscure other spectral details (McBride, 1986, 1989). No direct EPR evidence of Fe^{2+} species is obtained in soil mineral and organic components.

Divalent copper

Soil HS often show an anisotropic rigid-limit spectrum of the 'axial' type in the $g = 2$ region (Figs. 4b, c, and 5b, c), which is ascribed to Cu^{2+} ions (Senesi, 1992; Senesi and Loffredo, 2005, 2008; Senesi et al., 1986; Senesi et al., 1991). The nuclear spin of Cu is $I = 3/2$, thus its EPR spectrum should be split into four (i.e., $2I + 1$) features both at $g_{\parallel}$ and $g_{\perp}$. However, only the component at $g_{\parallel}$ is generally resolved partially into a quadruplet (Figs. 5b, b¹, c, c¹), while splitting of the $g_{\perp}$ component is not resolved. The EPR parameters of this spectrum are consistent with a $d_{x^2-y^2}$ ground state for Cu^{2+} ions held in square planar (distorted octahedral) coordination sites (tetragonal symmetry) as inner-sphere complexes with either only O ligands, such as carboxyls, phenolic hydroxyls, carbonyls, and, often, water molecules, or both O and N ligands (Fig. 6a), or even only N ligands (i.e., a tetraporphyrin site). The resolved pattern observed in some cases at $g_{\perp}$ is ascribed to superhyperfine coupling of the Cu^{2+} unpaired electron to N ligand nuclei ($I = 1$) (Senesi et al., 1991).

The values of spectral parameters also provide evidence of the contribution of a variable covalent bond (i.e., delocalization of the unpaired electron towards the ligands) for Cu^{2+} in HS. At small Cu^{2+} loading, covalent bonding is favored and complexation to amine-N groups is preferred to O ligands, whereas large Cu^{2+} loading in HS determines the formation of small covalency binding of Cu^{2+} largely to O-containing ligands. The accurate analysis of Cu^{2+} EPR patterns at $g_{\parallel}$, possibly with the aid of a computer simulated spectrum, often reveals the presence of two (or more) superimposed quadruplets, which proves the existence of different binding sites for Cu^{2+} in HS (Senesi, 1990a, 1990b, 1992, 1996).

Vanadyl ion

Soil HAs and FAs may feature a richly structured but relatively well-resolved pattern at about $g = 2$ (Figs. 4c and 5c) comprising two distinct overlapping axial rigid-limit spectra (Senesi, 1990a, 1990b, 1992, 1996; Senesi et al., 1991). One spectrum is the typical pattern of Cu^{2+} described previously, and the other comprises two superimposed hyperfine octuplets corresponding to the $g_{\parallel}$ and $g_{\perp}$ components of VO^{2+} ions (nuclear spin of V, $I = 7/2$) rigidly bound in square planar coordination sites as inner-sphere complexes with phenolate and possibly N ligands (large covalency, tightly bound forms) and/or surface carboxylate groups and water molecules (small covalency, relatively labile and exchangeable forms).

Fig. 6 Models for Cu^{2+} complexes in humic substances (a), on surfaces of gibbsite (b) and boehmite (c) in the presence of glycine, and on aluminium oxides and allophanes in the presence of phosphate (d).

Divalent manganese

The EPR spectra obtained for decomposing leaf litters (Figs. 4d and 5d) and some soil HAs and FAs have a well-resolved isotropic pattern in the region $g = 2$, which comprises six almost equally spaced principal lines and, possibly, 10 secondary lines (corresponding to forbidden transitions) of lesser intensity (Senesi, 1990a, 1990b, 1992, 1996; Senesi et al., 1991). The EPR parameters of such spectra are consistent with high-spin hexahydrated Mn^{2+} ($I = 5/2$) ions in outer-sphere complexes, bound by electrostatic forces to six O atoms of carboxylate and phenolate groups in a distorted octahedral environment.

Molybdenum (V) and (III)

The EPR spectrum of a peat soil HA complex with Mo(V) enriched in ^{95}Mo (nuclear spin, $I = 5/2$) features two distinct components, each split into two six-line hyperfine patterns at $g_{\parallel}$ and $g_{\perp}$, which are consistent with two different axially symmetric Mo(V)-HA complexes (Goodman and Cheshire, 1982; Lakatos et al., 1977). Treatment with 0.1 M HCl of these complexes produced a low-intensity EPR spectrum probably arising from Mo(III) species.

Spin derivatization studies

Spin labeling and spin trapping

The spin-labeling technique, which is the attachment of a simple and stable paramagnetic species such as the nitroxide radical to the compound of interest, is a powerful EPR method for evaluating the dynamics of HS macromolecules in solution, and, in turn, for providing information on the aggregation state, molecular conformation and micellar character of HS (Berliner, 1976; Senesi, 1990a, 1990b). Spin labels can also be used to investigate anisotropic molecular motion on mineral surfaces, which provides information on the nature of adsorption processes not obtained by other methods (Berliner, 1976; Senesi, 1990a, 1990b).

An interesting illustration of this technique is the use of two organic anionic nitroxide spin labels, provided with either a carboxylate or an organophosphate functional group, to study the nature of bonding to non-crystalline aluminium oxide, boehmite and gibbsite in aqueous suspensions (McBride, 1986, 1989). The EPR analysis revealed that both species were adsorbed rapidly onto the large surface area of aluminium oxide and boehmite, whereas only the organophosphate was adsorbed on gibbsite, with a loss in rotational motion, especially of the carboxylate. The values of motional restriction of organic radical anions on surfaces suggest that boehmite adsorbs carboxylate largely by ligand exchange with a single surface OH and organophosphate by bidentate binding, whereas non-crystalline aluminium oxide binds weakly to carboxylate by nonspecific electrostatic forces in addition to ligand exchange of surface OH.

The EPR spectra of the spin-label probe 5-SASL (stearic acid spin-label with nitroxide free radical in position 5 of the hydrocarbon chain) in HA suspensions suggest its bonding with surface hydrophobic sites of HA below pH 5, whereas these sites appear to be unavailable for bonding above pH 5. Kinetics of release of the nitroxide spin probes, neutral Tempol and cationic

Tempamine, from Ca-hectorite aggregates and or pastes measured by EPR suggest that the probes are not strongly sequestered. Nowadays, spin-labeled xenobiotics, e.g., pesticides, represent a promising application of EPR spectroscopy to study their distribution, fate and availability in soils.

The technique of spin trapping involves the reaction of the 'spin trap', such as nitrosobenzene, 2-methyl-nitrosopropene, 5,5-dimethylpyrroline 1-oxide (DMPO) or phenyl-N-t-butyl nitron (PBN), with a short-lived radical, for example, produced in HS by light irradiation, reduction, or raising the pH, to yield a relatively stable radical with an EPR spectrum that enables identification and quantification of the trapped short-lived radical (Thompson, 1990).

Metal spin probes

Complexation chemistry of humic substances

The EPR analysis of synthetic complexes obtained by the reaction of a paramagnetic metal 'probe' such as Cu^{2+} , Mn^{2+} , or VO^{2+} with natural soil HS can provide useful information on the chemistry of the 'residual' complexing capacity of HS towards metal ions and on the stability of the complexes formed (Senesi and Loffredo, 2005, 2008; Senesi et al., 1991). For example, when an FA is doped with 5.5–50.1% Fe^{3+} , the $g = 2$ signal is enhanced relative to the $g = 4$ signal, which suggests that Fe^{3+} is preferentially bound in easily exchangeable forms to the surface sites of FA (Senesi, 1990b). Evidence of inner-sphere complexes of Mn^{2+} coordinated octahedrally, possibly with carboxyl, phenolic hydroxyl and or carbonyl groups, is obtained for some soil HAs doped with Mn^{2+} at high pH (>8) or temperature ($>50^\circ\text{C}$) (McBride, 1986, 1989). Rotational correlation times obtained by EPR analysis combined with gel filtration chromatography data enable measurement of the dynamics of motion and stoichiometry of FA- VO^{2+} complexes in solution, and to obtain information on their molecular conformation and aggregation properties (Templeton and Chasteen, 1980). Quantitative EPR spectroscopy can also be used as a more sensitive, convenient, and faster technique, to determine weighted average equilibrium constants (K_c) for water soluble Mn^{2+} -FA complexes, which accord well with K_c values determined by ion-exchange methods (Gamble et al., 1977).

Ion exchange on layer silicates

The EPR spectroscopy confirms that metal ions such as Cu^{2+} , Mn^{2+} , VO^{2+} , and Cr^{3+} (chromium) retain their inner hydration sphere and considerable rotational mobility on exchange sites of layer silicate clays (McBride, 1989). For example, EPR spectra of exchangeable Cu^{2+} and Mn^{2+} on kaolinite indicate the presence of planar $\text{Cu}(\text{H}_2\text{O})_4^{2+}$ ions oriented parallel to the surface and with strong mobility (McBride, 1989; McBride, 1986). In contrast, an orientation-dependent rigid-limit EPR spectrum of Cu^{2+} is obtained for hydrated Cu^{2+} ions adsorbed on hectorite when the interlamellar spacing on the clay is limited to the equivalent of one or two molecular layers of water, which suggests considerable motional restriction for Cu^{2+} ions (McBride, 1986).

Chemisorption on mineral surfaces

The EPR analysis proves that paramagnetic metal ions at trace levels are bound rigidly in chemisorbed, nonexchangeable forms at isolated surface sites of soil oxides, hydroxides and aluminosilicates, whereas they are sorbed in exchangeable forms to layer silicate clays (Senesi, 1996). For example, Cu^{2+} has been proven to chemisorb at isolated sites on non-crystalline $\text{Al}(\text{OH})_3$ and microcrystalline AlOOH , possibly by the formation of one or two direct bonds between surface $\text{Al}-\text{O}$ groups and Cu^{2+} , which is favored at high pH (McBride, 1986, 1989). At low pH gibbsite can chemisorb small amounts (<0.5 mmole 100 g^{-1}) of monomeric Cu^{2+} that is oriented with its z -axis perpendicular to the (001) planes of the mineral. At pH >5 , a broad featureless resonance and reduction of the rigid-limit spectrum of Cu^{2+} appear suggesting the presence of different, possibly hydrolyzed and polymerized forms of Cu^{2+} on the surface. The large decrease in g -values and increase in $|A_{\parallel}|$ -values of the low-pH, gibbsite-chemisorbed Cu^{2+} with exposure to NH_3 vapors suggest that Cu^{2+} may form a complex with NH_3 while remaining rigidly bound to the oxide surface. The EPR data indicate that Cu^{2+} ions in the presence of the chelating ligand glycine absorb on microcrystalline gibbsite and boehmite in the form of ternary complexes in which Cu^{2+} coordinates simultaneously with one surface hydroxyl and one (on gibbsite) or two (on boehmite) glycine molecules, with orientation of the Cu^{2+} z -axis normal to the (001) sheets of the mineral (Fig. 6b and c) (McBride, 1986, 1989).

The EPR studies have shown that Cu^{2+} can be adsorbed by a direct bond (chemisorption) in nonexchangeable forms on allophanes and imogolite by both a preferential binuclear mechanism involving two adjacent AlOH groups and a weaker type of binding site probably involving isolated AlOH or SiOH groups (McBride, 1986, 1989). Furthermore, NH_3 can readily displace H_2O (water) and OH -ligands from chemisorbed Cu^{2+} , leading to the formation of ternary Cu^{2+} -ammonia-surface complexes. At low pH, Cu^{2+} has also been shown to chemisorb strongly to bidentate sites of titanium dioxide, whereas at higher pH a weaker complex is formed involving single $\text{Ti}-\text{OH}$ groups (McBride, 1986, 1989).

The EPR technique shows that Cu^{2+} is adsorbed on aluminium oxides and allophanes in the presence of phosphate forming a ternary complex with the phosphate coordinated to the axial position of a surface-bound Cu^{2+} (Fig. 6d) (McBride, 1986, 1989). Large amounts of phosphate suppress Cu^{2+} adsorption, apparently by blocking the coordination of Cu^{2+} to surface AlOH groups. Evidence from EPR has also shown that VO^{2+} can be co-adsorbed with phosphate on boehmite and aluminosilicates as an inner-sphere complex (McBride, 1986, 1989). Finally, EPR has proved that Cr^{3+} in the presence of selenite, phosphate, and fluoride is co-adsorbed on hectorite and montmorillonite with formation of ternary surface complexes (Charlet and Karthein, 1990).

Thermodynamic constants from EPR parameters

Metal spin probes can be used to estimate thermodynamic stability constants of metal-surface complexes from the EPR parameter g_{II} (Senesi, 1996). For example, there is a linear relationship between the g_{II} -value and corresponding formation constants of square planar Cu^{2+} complexes with hydrous- Al_2O_3 , TiO_2 and some silicas in the presence of bidentate ligands (Motschi, 1984). A decrease in the g_{II} value by 0.1 units corresponds to an increase in thermodynamic stability of about eight orders of magnitude. Based on such results, a major revision of current concepts of cation adsorption on layer silicates is possible.

Conclusions and perspectives

The EPR technique can provide unique information on the features of permanent organic free radicals indigenous to soil HS and in elucidating their interaction and bonding mechanisms with metal ions and organic chemicals. Furthermore, EPR enables measurement of the formation or disappearance of transient radical species in HS promoted by various environmental factors, which may help to elucidate several naturally occurring processes affected by HS, such as photosensitized reactions involving organic chemicals. Finally, EPR can provide unique insight into the oxidation states of metal ions and their mechanisms and sites of binding to HS, the identity of HS ligands involved, and the stability of metal complexes under different conditions.

The EPR shows promise for future more extensive and in depth research on the role of organic free radicals as potential initiators/activators/catalysts/mediators/antagonizers in one-electron redox processes occurring in soil and the direct physiological effects exerted by HS on seed germination, root initiation and plant growth in general. Furthermore, major advancement is expected by the application of spin derivatization techniques such as spin-labeling and spin-trapping, whereas ENDOR and ESEEM are expected to overcome some intrinsic difficulties of EPR such as improving its resolution in studies of randomly oriented soil components.

Abstract

This chapter presents the application of electron paramagnetic resonance (EPR) to soils, soil systems, and natural organic matter. The basic principles of EPR are introduced with a focus on the examples discussed within the chapter. The power and promise of EPR is illustrated using present-day applications (i) of high frequency EPR in environmental soil sciences, such as natural organic matter characterization and its binding of metals, (ii) of spin labels to probe pollutant sorption, and (iii) in the detection and characterization of a new class of compounds of interest known as environmentally persistent free radicals.

Key points

- EPR is a highly sensitive non-destructive technique
- EPR has seen some major recent advances, especially in terms of high field EPR and associated computational methods, that are allowing for detailed molecular level EPR studies on natural organic matter
- EPR can be used to monitor the association of metals and organic molecules with natural organic matter and whole soils
- EPR is an essential tool for studying environmentally persistent free radical

Introduction

Electron pair resonance (EPR, also known, especially in the past, as electron spin resonance [ESR]) can be viewed as the electron complement to nuclear magnetic resonance. The EPR has a long history of application in soil science, as illustrated by Lagerkrantz and Yhland (1963) and Atherton et al. (1967), primarily in the early studies on humic acids. Electron pair resonance spectroscopy has been used to study native and anthropogenic organic and inorganic components within soils, with studies ranging from humic acid and mineral characterization, to metal binding, to the production and fate of environmentally persistent free radicals. For a brief introduction and review of EPR applied to soils and soil components, please refer to Part I of this topic, *Historical perspective*, in the Encyclopedia of Soil Science. Advances in EPR and the resulting new applications of EPR to soils and soil-related components will be the focus of this chapter, with illustrative examples from the literature, preceded by a brief presentation of the basic principles of this technique.

Basic principles

This section presents the fundamentals of modern EPR with a focus on those that are particularly important to its application in the field of soil science. This is not meant to be a comprehensive introduction to the underlying principles or theory of EPR, but rather a short introduction based on a number of sources (Corvaja, 2009; Eaton et al., 2010; Weil and Bolton, 2007: the reader is referred to these references for further exploration).

Fundamentals

Spin: An intrinsic characteristic of electrons, and all elementary particles, is a quantum mechanical angular momentum known as spin, S . The term 'spin' is more customary than factual and refers to a behavior of an electron as if it were spinning (rotating about an axis), generating two distinct behaviors in the external magnetic field. An electron is a quantum particle and its behavior is controlled by quantum mechanics. For our purposes we will simply view electron spin as being in one of two states, usually indicated by α ($1/2$, spin-up, clockwise rotation) and β ($-1/2$, spin-down, counterclockwise rotation). Because of quantum mechanical considerations, we also need only to consider, S_z , the z -axis Cartesian component of S . Electrons are charged particles and when an electron spins, a magnetic moment will be created. The magnitude, S , of a magnetic moment expressed in $\hbar$ units, is given by:

$$|S| = \sqrt{S(S+1)}. \quad (1)$$

If the electron spin quantum number, S , is equal to $\pm 1/2$; then $|S| = \sqrt{3/4}$. For simplicity, we will only consider electrons, and hence only $+1/2$ (α) and $-1/2$ (β) states, for the remainder of this chapter.

Zeeman effect: As an electron has an associated spin, it will have an associated magnetic moment μ_e , proportional to S , as follows:

$$\mu_e = g \mu_B S, \quad (2)$$

where μ_B is the Bohr magneton and g is the Landé, or more commonly called the g -factor. If an external magnetic field, B , is applied, then there is an interaction between the external magnetic field and the magnetic moment. The energy (E) associated with this interaction can be calculated (to make this calculation straight forward and informative for how EPR experiments are executed, we will assume a magnetic field along the z -axis with a magnitude of B_0) as follows:

$$E = g|\mu_B|B_0S_z. \quad (3)$$

For half spin systems this means that we will have electrons with two different energies, as follows:

$$E_{\pm} = \pm(1/2)g|\mu_B|B_0. \quad (4)$$

With the energy difference between the two spin states given by:

$$h\nu = E_{1/2} - E_{-1/2} = \Delta E = g|\mu_B|B_0. \quad (5)$$

Eq. (5) shows that the energy difference between the two states scales linearly with the magnitude of the field applied.

A collection of electrons: For real samples, one is dealing with a large collection of spins, in the order of trillions or larger, which means that in a magnetic field there will be a population in a lower and higher energy state Eq. (4). There will a population difference between the lower and higher energy states, given by the Boltzmann distribution law:

$$N_{\alpha}/N_{\beta} = \exp\left(-\frac{g|\mu_B|B_0}{k_B T}\right), \quad (6)$$

where T is the absolute temperature of the lattice and k_B is the Boltzmann constant. Under typical conditions, the population excess between the two states would be 1/1000. Although this may seem exceedingly small, it is more than enough for a detectable EPR absorption signal as a microwave induced transition from a low to high energy state; the signal being proportional to the number of spins in the initial state.

Why is g not constant: Above, we have viewed electrons as free electrons; however, for those in a molecule the situation is more complex. To help to provide insight into this complexity, first consider an atom with a fully occupied shell and one additional unpaired electron. Here, all the electron spins are coupled except that for the unpaired electron. In this case, there are two contributors to the electron angular momentum: (i) the spin of the electron and (ii) the electron's orbital motion around the nucleus. A layer of complexity is added when we lose the spherical symmetry of an atom and replace it with the low (far from ideal) symmetry of a molecule. In the case of a molecule, the orbital angular momentum tends to zero, leaving only the electron spin component of the electron's angular momentum. In other words, we are back to where we started with a free electron, even though the electron is not free. The fact that the electron in question is not free means that when it is excited, it obtains an orbital angular momentum contribution. Therefore, when ground state and excited electrons mix, a small amount of orbital angular momentum is transferred to the ground state electron; this is known as the spin-orbit contribution.

At this point it is useful to consider spin-orbital coupling from a chemical point of view, which may be accomplished by treating the nucleus (or nuclei) simply as an orbiting positive charge that produces a second magnetic field, dB , at the electron. This means that rather than B_0 the field experienced is B_{eff} . With this in mind, we return to and expand on some of the previous mathematics, so that:

$$h\nu = \Delta E = g|\mu_B|B_{eff} = g_e|\mu_B|(B_0 + dB) = (g_e + dg)|\mu_B|B_{eff}. \quad (7)$$

Therefore, the g -value ($g_e + dg$) contains the all-important chemical information of the molecule's electronic structure.

The magnitude of the spin-orbital contribution depends on the size of the nucleus that possesses the unpaired electron. This means that metal complexes have a substantial spin-orbital contribution with their large nuclei. For organic radicals, on the other

hand, their atoms are light, i.e., small, therefore the spin-orbital contribution is small. Nevertheless, even small dg values provide important information, such as the identity of an atom that the unpaired electron is associated with (centered on), as presented below:

Carbon centered: $g \sim 2.002$ to 2.003 .

Carbon centered next to an oxygen: $g \sim 2003$ to 2004 .

O/N (oxygen/nitrogen) centered: $g \sim 2.004$ to 2.006 .

S (sulfur) centered: $g \sim 2.007$ to 2.010 .

External magnetic field: Although not discussed directly, there are two ways in which one can collect EPR data, namely by applying a fixed (constant) magnetic field (B_0) and varying the applied microwave radiation or by applying microwave radiation of fixed frequency (ν_0) and varying the applied magnetic field. Due to a range of technical issues, it has been easier to vary the frequency of the applied microwave radiation compared to doing that with the magnetic field. Thus, the standard is to have a fixed external magnetic field when carrying out EPR measurements. The applied magnetic field does not always have to be the same and there are various technical reasons as to why one may wish to have different fixed magnetic fields depending on the experiment. These different fields (in units of Tesla, T) are broken down into a series of ranges known as bands (wavebands) based on the external magnetic field and the associated frequency (or wavelength) of the microwave source, with the common bands summarized in Table 1.

Although traditionally EPR has been carried out at lower frequencies (low frequency EPR, LFEPR), for example within the X-band, higher frequency EPR, akin to NMR, has advantages in terms of resolution and sensitivity as well as increased orientation selectivity for distorted systems. However, until recently, with hardware limitations and the much higher frequencies utilized in EPR than NMR, there have been several technical barriers to high frequency EPR and its application beyond highly specialized EPR research centers. With the recent introduction of commercial high frequency EPR (HFEPR) systems, HFEPR should become more widespread in a range of scientific fields, including soil science.

Local magnetic fields: Within a real system, such as a molecule, nuclei that possess spin angular momentum are present and hence an associated magnetic moment may be at play and be affected by the magnetic field in an analogous manner to electrons, resulting in the nuclear Zeeman effect.¹ A system with spin angular momentum will produce its own magnetic field, meaning that nuclei with a spin angular momentum will cause electron spins to experience an additional magnetic field. In other words, there will be an electron–nucleus spin interaction, known as a hyperfine interaction, leading to hyperfine splitting within the EPR signal into two (for protium, normal hydrogen, ^1H , carbon-13, ^{13}C , phosphorus-31, ^{31}P , and nitrogen-14 ^{14}N) or three (for deuterium, heavy hydrogen, ^2H , and nitrogen-14, ^{14}N) components. Importantly, carbon-12, ^{12}C , and oxygen-16, ^{16}O , do not possess spin angular momentum.

If one takes a step back and reflects on the above paragraph, the essence is that, within a molecule with nuclei possessing spin angular momentum both electron spin components, S (EPR), and nuclear spin components, I (NMR components will be present, and can be extracted. This is the principle behind such experiments as EPR-electron nuclear double resonance, ENDOR; such experiments can be viewed, in a very simple way, as EPR detected NMR with the sensitivity of EPR.

Instrumentation

An electron paramagnetic spectroscopy (EPR) instrument consists of a number of components, as illustrated in Fig. 1. The most important components are the microwave bridge, consisting of the microwave source as well as a detector, the sample cavity in which the sample is inserted, the electromagnet to induce the Zeeman effect, and associated electronics. The microwave bridge is the heart of an EPR spectrometer as this is where the microwaves are generated and detected. Most of the time, the difference between

Table 1 The EPR bands in terms of approximate required magnetic field and frequency.

¹For a nucleus to have a spin angular momentum, it must have spin. A nucleus of an atom can be viewed as being made of protons and neutrons, collectively called nucleons, whose spins are then paired up in a similar manner to how electrons are paired in the different electron spin orbitals. The spin numbers of the protons and neutrons are then summed up, resulting in the nuclear spin. As is the case with electrons, up ($\uparrow$) and down ($\downarrow$) spins cancel each other, so the $I = 0$. Nuclear spin is more complex than electron spin, and follows these general rules: i) if the nucleus contains an even number of both types of nucleons, then I (nuclear spin) = 0 (e.g., the ^{12}C isotope (6 protons and 6 neutrons) and ^{16}O isotope, ii) if the nucleus consists of an odd number of nucleons, then I is a half integer, e.g., $\frac{1}{2}$ in ^1H , ^{13}C , ^{15}N , and ^{31}P , and (iii) if the nucleus contains an odd number of neutrons and an odd number of protons, then I is an integer e.g., 1 in ^2H or ^{14}N . It is the smaller particles called quarks that comprise neutrons (and protons) that give neutrons their spin. Quarks have charge in the form of $-\frac{e}{3}$ or $+\frac{2e}{3}$. A neutron consists of two $-\frac{e}{3}$ quarks and one $+\frac{2e}{3}$ quark, no combination of quark spins may result in a zero spin, explaining why neutrons have spin.

Fig. 1 A simplified block diagram of an EPR spectrometer.

the microwave energy emitted versus that reflected back by the sample is monitored. Hence, in addition to the microwave source and the detector, more electronics are needed. These additional electronics can best be explained by following the microwaves themselves. As the microwaves leave the source, they are split into two signals. The first signal is sent to the sample while the second signal is sent to the detector and acts as the reference signal. Both the sample and reference signal go through an attenuator. This attenuation step is essential to avoid saturation and allows the microwave power reaching the sample to be both accurately and precisely controlled. As the microwave energy makes its way to the sample, it goes through a circulator that directs the emitted microwaves to the sample and the reflected microwaves to the detector diode.

The sample of interest itself is placed in a cavity. The purpose of the cavity is to act as a resonator that amplifies the weak sample signal by storing this signal, so that it is not reflected back. A factor known as Q (proportional to the amount of energy stored versus energy dissipated) is used to determine the efficiency of the cavity, where the higher the Q the higher the sensitivity of the spectrometer.

Applications

Soils and soil organic matter

To obtain an EPR signal, unpaired electrons that give rise to paramagnetic systems must be present; for soils and soil organic matter this is made possible mainly by the presence of either the metal centers or organic radicals. For this chapter, we focus primarily on the organic radicals; the role of metal ions is only briefly mentioned (for a more in-depth review of the metal centers in EPR soil research, the reader is referred to the EPR chapter entitled *Historical perspectives* in the current edition). It should be noted that organic radicals within soils and soil organic matter can be divided into two classes, namely long-lived (persistent) and short-lived (transient). In real world soils and soil organic matter, both the naturally occurring persistent free radicals and transient species exist; the latter have been discussed more frequently in the scientific literature.

The majority of EPR studies on soils and soil organic matter² have utilized X-band or low frequency EPR that yielded broad and rather featureless EPR spectra. From these spectra three parameters have been derived, namely radical concentration (usually reported as spins gram^{-1} , typically in the 10^{16} – 10^{17} range), chemical information from the g -value (typically ranging from 2.0032 to 2.0043), and line width that may be informative in relation to radical heterogeneity. Linewidths are difficult to interpret as they are influenced by a range of factors such as the mobility of the radical, small to large variations within local environments surrounding the radicals, as well as chemical heterogeneity of the detected radicals themselves.

How much?; Or, spin counting: This is the quantitative aspect of EPR, and is, in some ways, technically the most difficult measurement. This is because of the nature of the EPR measurement and the fact that the spin content and its counting are usually obtained by comparison with a standard stable radical reference, e.g., diphenylpicrylhydrazyl (DPPH). This approach dictates that in order to compare samples quantitatively, the two samples must be measured in identical environments. Of utmost importance is sample placement within the cavity (a resonator in which microwave power is focused on the sample) because even the smallest deviations in the exact location can result in substantial variations in signal intensity, and hence, measured spins per gram. Approaches to alleviate this concern are to use a double cavity set-up or have the reference in a smaller concentric tube (a similar practice to that used in NMR). Other considerations when doing such an absolute comparison must be given to the power

²Due to the complex nomenclature within the soil community when it comes to soil organic matter, humic substances, humic acid, fulvic acid, humin, etc. we will utilize natural organic matter, or NOM.

Fig. 2 Equilibrium between quinone (Q), semiquinone ($\text{SQ}^{\bullet-}$) and hydroquinone (H_2Q) compounds.

saturation effects and background levels of the instrument, sample holder, etc. Relative spins gram^{-1} , especially if the sample tube is not moved during the experiments are, as a whole, more reliable. For an in-depth discussion of quantitative EPR the reader is referred to the excellent monograph by Eaton et al. (2010).

The nature of radicals within soils and NOM (natural organic matter) sample conditions also play a major role in how many spins gram^{-1} are detected. The majority of the radicals within soils and NOM are believed to be semiquinoid radicals which arise from the equilibria between phenolic and quinoid units (Giannakopoulos et al., 2005, and references there in), an example of this is the equilibrium between quinone (Q), semiquinone ($\text{SQ}^{\bullet-}$) and hydroquinone (H_2Q) compounds illustrated in Fig. 2. These equilibria are strongly influenced by sample conditions, especially pH, bound metal ions, and the isolation technique (Paul et al., 2006; Jerzykiewicz et al., 2002). The quinoidal radical model was particularly well illustrated by Ariese et al. (2004) in which a hydroquinone/quinone ($\text{H}_2\text{Q}/\text{Q}$) was compared to a very rare well resolved EPR spectrum of an NOM sample, Laurentian fulvic acid (LFA), in which most of the LFA EPR spectrum was modelled by the five line $\text{H}_2\text{Q}/\text{Q}$ EPR spectrum. The work by Paul et al. (2006) illustrates well the influence of pH on radical content for a large number of NOM samples; the pH of the isolation condition strongly influenced the spins gram^{-1} detected (as pH increased, so did the spins gram^{-1} and vice versa). This pH effect was much stronger than that of metal complexation, which has also been shown to influence the number of detected spins; the presence of Mn(II) (manganese), Ni(II) (nickel), Co(I) (cobalt), Fe(II) (iron), and Cu(II) (copper) metal ions caused a decrease in the number of spins detected (Jerzykiewicz et al., 2002). This spin quenching is believed to be due to an antiferromagnetic interaction of the metal ion's *d*-subshell with the unpaired electrons of the $\text{H}_2\text{Q}/\text{Q}$ complex. The reversibility of this effect has also been shown by Keeler and Maciel (2003) in which samples demonstrated higher spin counts after the removal of iron and other metal ions by treatment with aqueous hydrofluoride (HF) acid. However, for such metal ions as Zn(II) (zinc), Cd(II) (cadmium), Ca(II) (calcium), and Pb(II) (lead), the opposite was shown to be true, with spin counts increasing with metal binding (Jerzykiewicz et al., 1999).

In terms of spin counts (spins gram^{-1}), especially in absolute terms, i.e., not relative values, one must use caution when reporting them as they are based on observable EPR signals which, in turn, depend on how the data were collected and on the composition of the sample, including the conditions under which the sample was isolated. This means that there is a need for as much information as possible about how the sample was collected and the conditions under which the data were collected. If possible, metal ion content should also be presented.

What is it (g-value and more)?: While spins per gram can be viewed as the quantitative (*how much?*) side of EPR analysis, *g*-values can be viewed as the qualitative (*what is it?*) side of EPR analysis. As stated above, *g*-values for soils and NOM tend typically to range from 2.0032 to 2.0043, with a reported range of 2.003–2.005 (Christoforidis et al., 2007). These numbers raise the question as to how different 2.003 is from 2.005, or more precisely, are these numbers significantly different? The short answer is yes. The longer answer is that one should not focus on the whole number per se when comparing similar classes of radicals, such as organic radicals. The issue is that, unlike NMR, EPR values are not broken down to specific elemental ranges (e.g., carbon chemical shifts), therefore, changes within organic radical signals are in a seemingly narrow region. In reality, however, the difference between 2.003 and 2.005 and reported differences within this range are significant and highly reproducible. Nevertheless, when compared with NMR data, the *g*-value for NOMs has been of limited use for deriving detailed information on chemical composition. There are two main reasons for this: (1) the general use of X-band EPR spectrometers results in an isotropic *g*-value (g_{iso}) because there is relatively little anisotropy of *g* for organic radicals and (2) the heterogeneous nature of NOM leads to a broad statistical distribution of local environments and *g*-values that tend to average into a single broad peak. Yet, there are exceptions reported in the literature, as exemplified by Ariese et al. (2004) in which a reported well-resolved five-line spectrum was similar to that of a model $\text{H}_2\text{Q}/\text{Q}$ system and could be explained by coupling³ to the four protons within an aromatic ring. Fluorescence studies in addition strengthened and supported the EPR-based findings within this study. A closer examination of the EPR spectrum of the NOM used in the study revealed a small shift in the *g*-values that is consistent with electron withdrawing ring substitutions. Thus, in certain and rather rare circumstances with the aid of simulated data, *g*-values obtained from X-band EPR can yield structural information beyond a simple single *g*-value.

Higher magnetic fields in EPR (e.g., HF-EPR), as with NMR, allow for a greater Zeeman splitting, and therefore a wider frequency range. This, in turn, leads to a larger separation of the signal in the frequency domain, and higher resolution within the obtained

³Coupling arises due to the influence of the magnetic field of one spinning system within a magnetic field on another. This type of interaction is distance-dependent and it is short range.

spectrum. Consequently, at large enough magnetic fields, the g_{iso} signal will be deconvoluted into its three g tensor components, $g_{\text{iso}} = (g_x + g_y + g_z)/3$ (Christoforidis et al., 2007), as presented theoretically in Fig. 3. In particular, this is the case for the application of HFEPR to NOM. The power of HFEPR in the analysis of NOM was illustrated by Christoforidis et al. (2007) on four different humic acids (three from coal and one from soil), in which all four yielded well-resolved g_x , g_y , and g_z tensor components. Fig. 4 illustrates the advantage of HFEPR versus LFERP on a real humic acid sample, HA1. In addition, it was shown with spectral simulation that the EPR signal could be broken down into two radical types with different collective g_x , g_y , and g_z values that were prevalent at different pHs (the observed pH behavior was simple and reversible). These higher resolution data enable a more detailed structural analysis, especially with the aid of model compounds (semiquinone, β -carotene, and pheophytin radicals), to provide insights such as the unpaired electron being in a p -orbital, most likely conjugated p -orbitals, and the radical centers being most probably p -type, with carbon-centered radicals dominant at low pH and oxygen- or nitrogen-centered radicals dominant at high pH. Since this pioneering study, HFEPR has been used to study natural organic matter, especially in relation to metal binding.

Metal binding

Electron paramagnetic resonance has a long history in the literature in relation to metal binding. For reviews of those studies the reader is referred to the following work of Senesi (Senesi, 1990). As a whole, the majority of the metal EPR research focused either on the metal ion itself or some form of quantitative analysis (as discussed above), but did not focus directly on the NOM, with one notable

Fig. 3 A theoretical illustration of the increased resolution provided by HFEPR over LFERP as the g_{iso} is separated into g_1 , g_2 , and g_3 (e.g., g_x , g_y , and g_z) as the magnetic field and associated frequency increase. Reproduced with permission from Christoforidis KC, Un S, and Deligiannakis Y (2007) High-field 285 GHz electron paramagnetic resonance study of indigenous radicals of humic acids. *Journal of Physical Chemistry A* 22: 11860–11866, doi: 10.1021/jp0717692.

Fig. 4 Resolution advantage of HFEPR (left) over LFERP (right) for a humic acid (HA1) due to the ability to deconvolute the g_{iso} signal into its g_1 , g_2 , and g_3 contributions. Reproduced with permission from Christoforidis KC, Un S, and Deligiannakis Y (2007) High-field 285 GHz electron paramagnetic resonance study of indigenous radicals of humic acids. *Journal of Physical Chemistry A* 22: 11860–11866, doi: 10.1021/jp0717692.

exception being that on Pb(II). The development and application of HFEPR has allowed a re-examination of metal binding to NOM, especially from the NOM viewpoint through the resolution of g_x , g_y , and g_z tensors. A multi-metal study by Christoforidis et al. (2010) utilized the high resolution of HFEP to show that Mg(II) (magnesium) interacts with the NOM under study by purely electrostatic interactions and, in doing so, dramatically alters the H-dissociation of the type I and II radicals, as shown by pH-dependent studies. The same study used HFEPR to show that Mg (II), Cd(II), Sn(II) (tin), and Pb(II) have very different binding modes with NOM. For instance, Cd(II) binding is shown to alter the g tensors of both type I and II radicals, resulting in a less anisotropic spectrum, which suggests covalent binding. It was also found that Sn(II) bonds covalently to the NOM studied, and with the resolution of HFEPR it was also possible to observe (by subtracting spectra of the NOM studied after 2 h from that after 5 days of incubation with Sn(II)) the formation of a new type of radical within the NOM due to its binding with Sn(II). This new type of NOM radical formation with metal binding had been reported previously for Pb(II) when studied by X-band EPR; however, HFEPR has allowed new and significant insights into this phenomenon (Jerzykiewicz, 2004; Christoforidis et al., 2010), with exemplarily data presented in Fig. 5.

The new type of radical formed by Pb(II) binding to NOM has an unusually low g -value (~ 2.001 : Jerzykiewicz, 2004; Giannakopoulos et al., 2005), which is less than that of a free electron, and was initially explained by a localization of spin density on the Pb(II). This very unusual finding has continued to be investigated by Jerzykiewicz and co-workers using mainly a combination of EPR on NOM and model compounds in concert with density functional theory (DFT)-based calculations (Jerzykiewicz, 2004; Giannakopoulos et al., 2005) to gain a detailed molecular understanding of the situation. This is significant given its environmental importance in terms of Pb(II) speciation as well as radical formation within NOM. With the higher resolution provided by HFEPR, two complexes were found for the model compounds with different g tensor components. The DFT calculations were then able to model the experimental data using a two-step mechanism, in which a diamagnetic Pb(II) complex is formed and subsequently oxidized. From the point of view of NOM, this translates into Pb(II) being complexed by carboxyl oxygens and the hydroxyl oxygens then being protonated.

Spin labels

Not only can metal binding be monitored by EPR, but so can organic molecule (contaminant) sorption (binding/association) using organic spin labels (SLs). The inherent sensitivity of EPR is a major advantage because it allows for low concentrations of a pollutant to be monitored not just quantitatively but also qualitatively and non-destructively. There have been two major approaches to the use of SLs. The first is direct monitoring of the SL itself in the presence and absence of NOM under different conditions, while the second is monitoring of the effect of SL-induced paramagnetic relaxation on the NMR signal of NOM.

SL monitoring: In Ferreira et al. (2001), EPR monitoring of an SL and its sorption to a soil-extracted humic acid (HA) showed that the EPR spectral signal of a N-oxyl-4',4'-dimethyloxazolidine derivative of 5-ketostearic acid (5-SASL) was clearly visible over the inherent (radicals native to NOM) organic radical signal of the NOM sample under the conditions used in the study, including the hyperfine splitting within the 5-SASL EPR spectrum. By varying the pH, and hence conformation of the NOM and monitoring

Fig. 5 A set of HFEPR spectra for Pb(II) bound to a soil humic acid (HA) at three different pHs illustrate how the resolution of the HFEPR technique enables the identification of two unique radical species within this system. Reproduced with permission from Christoforidis KC, Un S, and Deligiannakis Y (2010) Effect of metal ions on the indigenous radicals of humic acids: high field electron paramagnetic resonance study. *Environmental Science and Technology* 44: 7011–7016, doi: 10.1021/es101708f.

the linewidths of the 5-SASL EPR signal, the authors proposed a two-binding site (interior and exterior) model, in which the interior sites depended strongly on NOM conformation (determined by pH dependence) and the lower affinity exterior hydrophobic sites became more important at higher pH (>5). Aleksandrova (2013) then extended this research to soils and SLs differing by a single functional group on the opposite side of the ring to the oxygen-centered nitroxide radical, utilizing a base spin label called tetramethylpiperidin-1-oxyl (TEMPO), with an example of the information-rich spectra presented in Fig. 6. This research, once again, used the hyperfine EPR spectral features within the EPR spectrum of the SL, in which there was a shift of the outer lines inwards showing a change in the polarity of the SL as it interacted with the soils. Furthermore, changes in the linewidths of the EPR signal, and hence, mobility of the SLs were noted with an increase and decrease in mobility for the 4-hydroxyl TEMPO and 4-amino TEMPO SLs, respectively, with increasing incubation time. In addition, the signal of the native soil radicals decreased as the SL interacted with the soil over time. This study showed that EPR can be used to probe the chemical interaction of SL mimicking pollutants in soils and allows one to gain insight into the mechanism of binding with soil organic matter, including the role of pollutant functional groups. Matthies et al. (2016) expanded the work of Aleksandrova (2013) by utilizing amino-functionalized SLs in the form of 4-amino TEMPO and 2,5,5-trimethyl-2-(3-aminophenyl)pyrrolidine-1-oxyl, anilino-NO, to compare aliphatic versus aromatic functionality in terms of NOM binding with Leonardite humic acid. This study, once again, revealed the importance of functionality when a pollutant binds to NOM; anilino-NO showed two binding motifs compared with a single motif for 4-amino TEMPO. The fitting of simulated spectra of the experimentally-determined spectra yielded a rotational correlation of 95 ps for 4-amino TEMPO, which indicated an ionic type interaction with the NOM. For the anilino-NO, two rotational correlation times were determined and assigned to weak and strong interactions within the NOM. Further kinetic studies with laccase and N-tert-butyl- α -phenylnitrone (radical scavenger) strongly indicated that a covalent bond forms between the anilino-NO and the NOM. Matthies and co-workers (Ricke et al., 2021) extended this approach further with a model humic-clay system to demonstrate that spin labeled sulfonamides (SL-SDZ) were covalently bound to quinone moieties within NOM and that the clay mineral increased immobilization of the SL-SDZ.

Paramagnetic Relaxation Probes: The electron magnetic moment that is at the core of EPR is about 650 times greater than the magnetic moment of a proton. This magnetic moment perturbs the local magnetic field, and induces relaxation pathways through dipolar coupling between the electron and nucleus (r^{-6} distance dependence, leading to a strongly localized effect), which results in fast relaxation of the nuclear magnetic moment and, in turn, line broadening and eventual disappearance of the NMR signals. The longer the relaxation time of the electron magnetic moment, the more it perturbs the NMR signal (this is due to the much longer nucleus relaxation times in its shielded local environment than that of an electron). This phenomenon is known as paramagnetic relaxation. Thus, a radical not only reveals its local environment by its EPR signal but also by the way it eliminates the NMR signal. The research of Bleam and co-workers (Chien et al., 1997) and that of Pignatello and co-workers (Lattao et al., 2012) are two examples of this phenomenon at work. Chien et al. (1997) used EPR to reveal that TEMPO, via its hyperfine coupling, interacts with the surface of the NOM studied. The work then used gadolinium ethylenediaminetetraacetic acid, Gd-EDTA, (hydrophilic paramagnetic probe) and TEMPO (hydrophobic paramagnetic probe) to show that TEMPO and not Gd-EDTA induces paramagnetic relaxation (via ^{19}F NMR) within an ^{19}F -labeled atrazine sorbed to the solubilized NOM. This provided strong evidence that atrazine sorbed to the hydrophobic surface domains within the NOM studied. Lattao et al. (2012) utilized TEMPO and 4-hydroxyl TEMPO paramagnetic probes as pollutant surrogates. Electron paramagnetic resonance was used to show, by line broadening, that TEMPO was confined within the Pahokee peat humic acid NOM. The research by Lattao et al. (2012) did not reveal any specific functional NOM group binding by either of the two paramagnetic probes examined by paramagnetic relaxation.

Environmentally persistent free radicals (EPFRs)

In the past decade or so, a new class of organic compounds of concern have come to the forefront of environmental research, namely environmentally persistent free radicals (EPFRs), and EPR has been the central tool in their identification, classification, and study. The EPFRs result from the formation of an organic radical within an environmental matrix, including soils. Although naturally occurring environmentally persistent free radicals, nEPFRs, have been known for decades as illustrated by the early application of EPR to NOM samples, including soil organic matter within whole soils, a second class of EPFRs has been found to be the product of organic pollutant transformation. In the work of de la Cruz et al. (2011, 2014) EPR was essential in showing that EPFRs are at much higher concentrations within soils at a range of polluted sites, and the soil fraction(s) that contained the EPFRs. Further research by others has shown just how prevalent these soil-associated EPFRs are within the environment. Electron paramagnetic resonance has been central in determining that these soil EPFRs arise from two main mechanisms, namely (i) atmospheric deposition, in situ burning, or biochar incorporation and (ii) redox reaction with a metal center.

Metal Center Driven: With the use of EPR and soil fractionation, Fig. 7, de la Cruz et al. showed that ~90% of the EPFRs at a polluted wood treatment site were associated with the mineral/humin fraction of the soil and were oxygenic carbon-centered (g -factor, 2.0031) in nature. Further, by combining XAFS and EPR, Nwosu et al. (2016a, b) showed that Fe(III)- and Cu(II)-exchanged montmorillonite clays, when dosed with phenol, produced oxygenic-carbon centered (g -factor of 2.0034) EPFRs under environmentally relevant conditions, and provided clear evidence that this effect was due to the transfer of an electron from phenol to the Fe(III) or Cu(II) center. Based on the long lifetime (persistence) and resistance to oxygen degradation determined by EPR (as well as XRD) data, the EPFRs were thought to be formed interstitially. In addition, based on the loss of intensity of the EPR signal, humidity was found to be a major EPFR deactivator, while the presence of a synthetic surrogate soil organic matter was shown to induce even longer periods of EPFR persistence. Furthermore, EPR spin trapping using 5,5-dimethyl-1-pyrroline-N-oxide (DMPO), revealed that EPFRs formed in metal exchange clay systems could induce the formation of biologically relevant reactive oxygen species. Other work on montmorillonite clay systems has also shown with EPR analysis that EPFRs form under environmentally relevant conditions, with the transformation of anthracene into either a carbon, g -factor: 2.0028–2.0030, or an oxygenic carbon-centered radical, g -factor: 2.0032–2.0038 respectively (Jia et al., 2016).

Reactive Oxygen Species: Electron Paramagnetic Resonance has also been key in understanding the role of EPFRs in the decomposition of organic pollutants. The generally accepted mechanism involves the EPFR-generated reactive oxygen species (monitored by EPR in DMPO trapping experiments) which, in turn, react with the pollutant of interest (along the line of Fenton chemistry). However, through detailed EPR analysis Yang et al. (2016) showed that EPFRs within biochars decomposed *p*-nitrophenol by an electrophilic attack.

Summary

Within soil science the most popular magnetic resonance technique is nuclear magnetic resonance, NMR, due to its high resolution and ability to analyze samples selectively by nuclear spin manipulation. Its electron counterpart, electron paramagnetic resonance, or EPR, spectroscopy, has been much less popular. There are several reasons for this, including hardware accessibility and difficulty in spectral interpretation; however, the major reason has been the low resolution of the majority of soil-focused EPR spectra reported within the literature, especially for organic-focused research. However, as the discussion and selected examples above demonstrate, in the world of soil science EPR research has an important place in the modern era; therefore, the much greater sensitivity of EPR compared with NMR holds great promise for the technique. A major factor for delivering on this promise is how EPR experiments and EPR data are analyzed. The advancement of EPR and the unique insights it enables in soil research results from careful experimental design, taking the limitations of the technique into consideration and, in some cases, turning them into an advantage. An example of this is the use of spin labels as surrogate pollutants with the sensitivity of the hyperfine structure within the EPR spectrum of these spin labels serving as a probe for soil sorption environments. The spectral interpretation required in such experiments has been greatly aided by modern computational methods. It is also clear that EPR complements and is complemented by other techniques to allow for a fuller interpretation of the data obtained. Finally, the introduction of commercial HF-EPR instruments and the associated higher resolution spectral data enable acquisition of higher quality and more information-rich EPR spectra for soils and soil systems, and a better understanding of radical entities within these systems.

Abstract

Fluorescence spectroscopy is a noninvasive, nondestructive and highly sensitive technology that requires minimal sample pretreatment. Therefore, it is widely used in the study of soil components. This chapter describes the principles of luminescence of fluorescent substances and the fluorescence instrument used. In addition, the basic concepts of fluorescence efficiency, lifetime, intensity, polarization, and quenching, and environmental factors that affect the luminescence of fluorescent substances are also elaborated. Finally, recently developed fluorescence spectroscopy techniques commonly used in the detection of soil organic components are introduced, including fluorescence correlation spectroscopy, laser induced fluorescence spectroscopy, X-ray fluorescence spectroscopy and time-resolved fluorescence spectroscopy.

Key points

- The luminescence principles of fluorescent substances are elaborated.
- Important fluorescence characteristic parameters are introduced.
- Some fluorescence spectroscopy techniques commonly used in the detection of soil organic components are introduced.

Introduction

Classical monodimensional fluorescence spectroscopy in the emission, excitation, and synchronous scan modes and total luminescence or tridimensional (3D) fluorescence are noninvasive, nondestructive, and highly sensitive techniques that require minimal sample pretreatment. Therefore, fluorescence spectroscopy is widely used in the study of organic and inorganic soil components. With the rapid development of fluorescence technology, fluorescence spectroscopy has proven to be a very promising and useful, especially as an in-situ method for determining soil organic components. The diversity of inherent fluorescence structures in soil organic components has provided invaluable information on their structural and functional chemistry and reactivity as a function of relevant environmental factors such as pH and ionic strength.

Basic principles, methodology, and instrumentation

The fluorescence phenomenon

Every molecule has a series of closely spaced energy levels (Fig. 1). After a molecule absorbs energy, such as light, an electron is promoted from the ground state, S_0 , to an excited singlet state, S_1 , S_2 , etc. Typical transitions of this kind are very likely in complex molecular systems containing atoms with lone pairs of electrons, such as oxygen or nitrogen, and aromatic or aliphatic conjugated unsaturated systems capable of considerable electron delocalization. Any excited state electrons then relax to the lowest vibrational

Fig. 1 Jablonski energy diagram. Adapted from Davidson MW (2009) Alexander Jablonski, PhD: Fluorescence Spectroscopy. *Laboratory Medicine* 40: 694–695.

level of that state, and, subsequently, energy is released by ‘internal conversion,’ dropping the electron to the lowest vibrational level of the lowest excited state, S₁. Relaxation from the S₁ state, which has a lifetime of 10⁻⁹ s, to the ground state S₀ can then occur by different mechanisms (Fig. 1). Recently, (Kim et al., 2021) found that the lifetime of S₁ is greatly increased to 1.80 ns at the zero-point level when catechol (a toxic organic compound, C₆H₄(OH)₂) is complexed with water. The above relaxation processes include: (1) the radiative photo process of fluorescence, which involves the emission of photons less energetic than those absorbed because of the energy loss incurred during internal conversion processes; and (2) various nonradiative processes, such as: (a) internal conversion processes from relaxation through internal vibrations or through collisions with solvent and or solute molecules; (b) transfer of energy to another compound with similar wavelengths and close to each other, resulting in a photochemical reaction or the formation of an excited-state dimer (excimer) or excited-state complex (exciplex) which then emits photons at longer wavelengths than fluorescence; and (c) intersystem crossing to a triplet state, T₁, that has a lifetime much longer (often >10⁻⁵ s) than its S₁ precursor, which is followed by either a delayed release of energy known as phosphorescence, or by relaxation through internal conversion processes.

Instruments and experimental procedures

In general, fluorescence measurements require only a small amount of sample preparation. Solutions and diluted colloidal suspensions (<1 g solid⁻¹) can be placed directly into quartz cells, whereas the use of dense colloidal suspensions should be avoided because these result in increases in light scattering and absorption, and a subsequent decrease in signal-to-noise ratio. Furthermore, the inner filter effect caused by excessive fluorophore concentration or coexistence with other absorbable species cannot be disregarded. The inner filter effect can be divided into two types when the solution concentration is too high: (1) after the incident light is strongly absorbed by the fluorescent substance in the front part of the sample cell, the incident light received by the fluorescent substances in the back of the sample cell will be greatly weakened, resulting in a decrease in the fluorescence intensity; (2) the absorption of incident light by impurities in the solution reduces the excitation light intensity of the fluorescent substance.

The principal components of a fluorescence spectrophotometer used for steady-state measurements are shown schematically in Fig. 2. The excitation energy is provided by a high-energy continuous light source, usually a xenon discharge lamp. Other light sources, such as a pulse source, a light-emitting diode source and long-lived xenon lamps, have been widely used in recent years. Here a xenon arc lamp is used as an example (Fig. 2). The excitation monochromator contains two concave gratings of reduced hetero astigmatism. Both monochromators are motorized and can scan wavelengths automatically. Fluorescence is obtained with a detector, such as photomultiplier tube and quantified with an appropriate electronic device. The output component is typically displayed graphically and stored digitally. The desired excitation wavelength is selected by passing incident radiation through a monochromator before it enters the sample cell, preferably a quartz cell. Radiation emitted by the sample is generally monitored at an angle of 90 degrees to the excitation radiation to minimize signal distortion from light scattering, or by front-surface detection for a solid sample. Wavelength selection of the emitted radiation is obtained with another monochromator. The light emitted is then

Fig. 2 Schematic diagram of the fluorescence spectrophotometer using a xenon arc lamp as an example. Adapted from Lakowicz JR (2006) *Principles of Fluorescence Spectroscopy*, Third Edition. New York: Springer. 28–29.

measured by the detector, usually a photomultiplier tube. The detector is usually coupled with a device camera (for example, charged-couple device (CCD) camera), high speed camera, or other imaging devices. The instrument is completed by a readout device, usually a computer, or, preferably, a microprocessor for data analysis.

Temperature control devices such as thermostatic cell holders, circulating water temperature controllers, and a semiconductor thermostatic device to control sample temperature and cell stirrers have been added to most commercial spectrofluorometers. Laser-induced fluorescence spectroscopy (LIFS) has been used widely for exploring the properties and environmental behavior of soil organic components. The entire instrument can be put under computer control with several benefits in precision, calculation of Φ , and corrections for factors affecting fluorescence, such as the inner-filter effect and photodecomposition. Time-resolved fluorescence (TRF) spectra or fluorescence lifetime measurements, measures the time a molecule is in the excited state. It involves the use of pulsed or modulated light sources and a rapid-detecting photomultiplier, a photodiode array, or a time-correlated single-photon counter. Fluorescence lifetime, a widely used method for the time domain, includes time-dependent single photon counting (TCSPC), generating a time of pulsed photon arrival by pulse sampling and a time-gated histogram to quantify the fluorescence decay curve directly (Bitton et al., 2021). The frequency-domain method measures the amplitude and phase shift of the fluorescent signal in response to modulated excitation light (Alfonso-Garcia et al., 2021). Polarized fluorescence measurements can be obtained by adapting a conventional instrument. Briefly, the appropriate oriented polarizers are placed between the excitation monochromator and the sample, and between the sample and the emission monochromator.

Fluorescence spectra

Conventional monodimensional fluorescence spectra can be obtained in three modes: emission, excitation, and synchronous-scan excitation on samples dissolved or suspended in liquid. The emission spectra were recorded by measuring the relative intensity of radiation emitted as a function of wavelength at a constant excitation wavelength. The excitation spectra were recorded by measuring the emission intensity at a fixed wavelength when changing the excitation wavelength. According to the relationship

that the excitation and emission wavelengths have with each other during simultaneous scanning, synchronous fluorescence spectrometry is subdivided into four types: (1) constant wavelength; (2) constant energy; (3) variable angle; and (4) matrix isopotential synchronous fluorescence spectrometry. The synchronous-scan technique can selectively increase the intensity of specific peaks, thus improving the resolution of spectral structure by decreasing the intrinsic broadness and overlapping of bands that occur in emission and excitation spectra of molecularly complex and heterogeneous multicomponent samples.

Total luminescence or 3D fluorescence spectra provide a complete representation of the fluorescence spectral features of a sample in the form of an excitation-emission matrix (EEM), in which fluorescence intensity is measured as a function of the excitation wavelength on one axis and emission wavelength on the other. The EEM spectra can be compared using the uncorrected matrix correlation (UMC) method. The UMC value equals 1 where the two matrices are identical and decreases towards zero with decreasing similarity between them. For the fluorescence zone integration (FZI) method, it could quantify differences in EEM among various samples, and measure the continuum of binding sites in metal and organic complexes of a sample. However, the relatively poor data processing efficiency of the FZI method limits its application for analyzing a large number of environmental samples. Recently, EEM combined with parallel factor (EEM-PARAFAC) analysis provides detailed spectral information from the fluorescence spectrum of the soil organic component (Qin et al., 2020). The accuracy and efficiency of multi-component fluorescence spectrum analysis is improved by separating the fluorescence signal into relatively independent components, especially for a large number of samples (Ravansari et al., 2020).

Fluorescence efficiency, lifetime, and intensity

Fluorescence efficiency, or quantum yield, Φ_f , measures the effectiveness with which the adsorbed energy is reemitted, and is defined as the ratio of total energy emitted as fluorescence to the total energy adsorbed. Absolute measurements of efficiency are difficult because they require calibrated sources and detectors. However, the relative fluorescence efficiency of a sample, Φ_s , can be obtained easily by measuring the fluorescence intensity of a dilute solution (I_k) of a standard of known efficiency, Φ_k , such as quinine sulfate, and that of the sample (I_s):

$$\Phi_s = \Phi_k (I_s q_k A_k / I_k q_s A_s), \quad (1)$$

where the I values are determined by integrating the area beneath the corrected fluorescence spectrum, q is the relative photon output of the source at the excitation wavelength taken directly from the curve, and A is the absorbance.

Fluorescence lifetime depends on the molecular species and is sensitive to environmental factors such as conformation and binding state of the absorbing molecule, temperature, pH, or solvent viscosity. Fluorescence lifetime (τ), refers to the probability of finding a given molecule in the excited state at time t after the excitation light source is turned off, and represents the mean lifetime of the excited state. The value of τ can be calculated by measuring the fluorescence intensity I at time t , $I(t)$, according to:

$$I(t) = I_M \exp(-t/\tau) \quad (2)$$

where I_M is the maximum intensity with the excitation light source on, i.e., during excitation, and t is the time elapsed after the excitation light source is turned off.

Fluorescence intensity, I , depends on the molar concentration of the adsorbing species in very dilute solutions, C , and the fluorescence efficiency, Φ_f , according to:

$$I = \Phi_f I_0 [1 - \exp(-\epsilon bC)] \quad (3)$$

where I_0 is the intensity of incident radiation, ϵ is the molar absorptivity at the excitation wavelength, and b is the path length of the cell. For very dilute solutions, where ϵbC is sufficiently small, Eq. (3) reduces to a linear relationship:

$$I = \Phi_f I_0 \epsilon bC \quad (4)$$

and the fluorescence intensity is essentially homogeneous throughout the sample. When ϵbC increases, the fluorescence intensity is no longer homogeneous within the cell but is increasingly localized at the front surface of the cell, thus the fraction of fluorescence measured by the common detection system is smaller (inner-cell effect). To avoid this effect, instruments are designed to examine an area at the front of the cell rather than at the center.

Limitations and problems

Fluctuations in intensity of the exciting light source, variation in instrument sensitivity of the detection system, and other factors related to the instrument may cause distortion and variation of instrument's response. The shape of the excitation spectrum should be identical to that of the absorption spectrum of the molecule, but differences may be observed due to artifacts arising from variation in the light source intensity with wavelength and other causes. The shapes of emission and excitation spectra should be independent of the wavelength of the exciting radiation and the wavelength at which fluorescence is measured, but spectra are often wavelength dependent. In practice, however, the variations expected are likely to be small when the fixed excitation or emission wavelengths used are varied within a limited range of values, i.e., between 320 nm and 370 nm and 520 nm and 570 nm,

respectively. Light-scattering effects such as Rayleigh, Tyndall, and Raman effects may also influence the fluorescence spectra recorded to a varying extent.

Corrections accounting for instrument related artifacts and for scattering effects should be applied to fluorescence spectra, particularly when quantitative comparisons are made between spectra measured on a variety of spectrofluorimeters by different operators. However, comparisons of uncorrected fluorescence spectra may be allowed on a qualitative basis when they are recorded with the same instrument using the same experimental conditions.

Recently, the following problems have usually occurred with in situ detection and the investigation of soil organic components. First, the environmental matrix is complex, and thus, there is usually fluorescence interference caused by other complex components when detecting the target compounds. Second, the complex and changeable environment and other environmental factors may lead to the distortion and change of response by the instrument during field in-situ investigation and research. Stability of the instrument is required to be good because of fluctuation in the intensity of the excitation light source and the change in sensitivity of the detection system in the complex in-situ field measurement environment. In addition, the in-situ field investigation has certain requirements for the portability of the instrument, the adaptation of type of power supply, and the accuracy of data.

Molecular and environmental factors affecting fluorescence

Several molecular properties can affect fluorescence intensity and wavelength. In particular, atoms and ions of large atomic number, such as halogens and paramagnetic metals, and the decrease in fluorescence efficiency of a fluorescent organic compound. Increasing the extension of the π -electron system increases fluorescence and shifts emission wavelengths towards longer values. Steric hindrance generally reduces fluorescence, whereas increasing rigidity of the molecular structure increases it. Electron-withdrawing groups, such as carbonyls and carboxyls, largely reduce fluorescence intensity, whereas the opposite is true for electron-donating substances such as hydroxide, alkoxide, and amino groups. Further, all these groups shift fluorescence to longer wavelengths.

Several environmental factors can also affect the fluorescence response of a sample. For example, fluorescence efficiency is decreased by temperature increase, or by a heavy atom in the solvent molecule or co-existing solute molecules containing heavy atoms, whereas it is increased by increasing solvent viscosity. Fluorescence wavelength is usually shifted to longer values with an increase in solvent polarity. Fluorescence intensity is reduced by increasing solute-solvent interaction, e.g., by hydrogen bonding. Therefore, heavy-atom solvents and hydrogen-bonding solvents should be avoided when possible. However, compared with non-polar solvents, wavelength of the fluorescence signal in aqueous solution is usually red shifted. For example, shift of the fluorescence spectrum when measuring polarized fluorescence is caused by the organic solvent effect.

Light absorption by the solvent, large concentrations of a fluorescent solute, the presence in solution of a solute that absorbs radiation together with the fluorescent molecule, or a solute that absorbs the fluorescence of the sample molecule, give rise to the so-called 'inner-filter' effect that causes quenching of the fluorescence of the sample. This effect can be reduced by selecting a suitable excitation wavelength, diluting the sample, viewing fluorescence closer to the front surface of the cell, and or using the method of standard additions or a correction factor.

The pH of the medium affects fluorescence spectra of acidic or basic aromatic compounds by rapid proton transfer reactions that occur to various extents during the lifetime of the excited state. Dissolved oxygen in organic solvents is an important reason for the quenching of organic molecules' fluorescence. For example, the fluorescence of polycyclic aromatic hydrocarbons (PAHs) is easily and dynamically quenched by dissolved oxygen in nonpolar solvents, resulting in a decrease in the quantum yield of PAHs. This dynamic quenching mechanism results from inactivation of the fluorophore in the absence of photon emission through collision with molecular oxygen during its excited state lifetime. This effect can be easily eliminated by bubbling nitrogen through the solution or by the addition of chemical oxygen scavengers, such as sodium sulfite (Na_2SO_3), calcium chloride (CaCl_2) and zinc (Zn) reduction for oxygen scavenging. Metal ions, especially paramagnetic ions, are also fluorescence quenchers, even where they do not form complexes with the fluorescent molecule. Metal quenching can be reduced markedly, e.g., by diluting the sample.

Fluorescence quenching

The process of physical or chemical interaction between fluorescent substance molecules and solvent or solute molecules, which lead to the decrease in fluorescence intensity, is called fluorescence quenching. The quenching process competes with the luminescence process to shorten the lifetime of the excited state of the luminescent molecule. Quenching may occur in the interaction between the quencher and excited state molecules of the fluorescent substance. Interactions between the quencher and ground state molecules of the fluorescent substance may also occur. The former process is called dynamic quenching, and the latter is called static quenching. In the process of dynamic quenching, the excited state molecules of the fluorescent substance lose their excitation energy and return to the ground state by energy or charge transfer through collision with quencher molecules. The efficiency of dynamic quenching is controlled by the lifetime of the excited state molecules of the fluorescent substance and concentration of the quencher. In static quenching, the quencher reacts with fluorescent substance molecules in the ground state, and the resulting complex does not usually emit light. Dissociation of the complex may be slower, so that decay of the exciplex to the ground state by a nonradiative pathway is more efficient. On the other hand, formation of the ground-state complex also reduces fluorescence intensity of the fluorescent substance because of competition with ground-state molecules of the fluorescent substance to absorb the excitation light. In general, fluorescence quenching methods are more sensitive and selective than direct

fluorescence assays. The emission intensity of a fluorescent species can be quenched by its association and or adsorption to organic and inorganic substrates. Fluorescence quenching is widely used in the titration of humus and quantitative determination of metals in soil.

Fluorescence polarization

After the fluorescent substance has been irradiated with polarized light in a single plane, it can absorb light energy and jump into an excited state. When it returns to the ground-state, it releases energy and emits polarized fluorescence in a single plane. The degree of polarization of polarized fluorescence is inversely proportional to the speed at which the molecule rotates when the fluorescent substance is excited. Fluorescence polarization methods can be applied to study the conformation of a fluorescent organic molecule and the sorption or binding of a fluorescent organic pollutant to a variety of environmental sorbents. Any process that causes a decrease in the rate of rotation of a fluorophore, i.e., a variation in its size, during the lifetime of the excited state, including change of conformation, adsorption on suspended particulate matter, or binding to dissolved materials, decreases the polarization. For example, fluorescence polarization can be used to measure changes in the rate of rotation of humic acids in soil, thereby inferring configurational changes in them.

Fluorescence correlation spectroscopy

Fluorescence correlation spectroscopy (FCS) is a powerful tool for detecting molecular dynamics by analyzing the intensity of fluctuations emitted by biomolecules as they diffuse and diffuse in a focused light. Compared with other kinetic oriented methods, FCS has a much wider measurable time frame, from nanoseconds (ns) to seconds (s), with greater sensitivity achievable at the single-molecule level. At present, FCS technology is widely used to characterize kinetic mechanisms, concentration dependent diffusion, and clustering of cell surface receptors in solution. Specifically, the correlation FCS technique with laser light (excitation at 488, 514 nm or 671 nm) is focused on the sample using confocal optics, thus obtaining an open, illuminated volume element that is called 'confocal volume'. The volume obtained by conventional diffraction-limited FCS is about 200 nm in size laterally and 600 nm axially. In the absence of chemical processes, temporal variation in measured fluorescence intensity in the confocal volume can be attributed uniquely to translational diffusion of the fluorophore. These variations can be analyzed with an autocorrelation function that includes a parameter, τ_D , which is the diffusion time characteristic of the particle under study in the confocal volume. The system can be calibrated with a Rhodamine 6G (R6G) standard that has a known diffusion coefficient. The values of diffusion times for R6G and the sample in each condition are then determined from the best fitting autocorrelation function, and is finally used to calculate the diffusion coefficient of the fluorescent sample.

The emergence of new technologies has expanded the development of FCS technology. Fluorescence cross-correlation spectroscopy (FCCS) is a variant of FCS based on the principle that the fluctuations in fluorescence of two fluorescent objects are correlated temporally (Fig. 3). With a laser of a desired wavelength, fluorescence is collected by the objective, separated from the excitation light by the dichroic mirror and focused by the tube lens in a pinhole. The pinhole collects only the fluorescence from the focal plane that goes to the detectors for correlation analysis. In the case of FCCS, only if the two species interact and diffuse together in the confocal volume (II), will the correlation between both signals result in a cross-correlation (III). Otherwise, the count rate graphs do not match (IV) and the correlation function will be zero (V). Once the signal has been obtained, different software packages can be used to analyze the data to obtain the diffusion coefficient or diffusion time of the measurements, as well as the number of particles inside the confocal volume.

Two-dimensional correlation spectroscopy (2D-COS) is an emerging spectral analytical technique that has been extensively used to investigate the environmental interactions between dissolved organic matter (DOM) and metals that can be toxic. The 2D-COS analysis provides better spectral resolution, specifically by obtaining a series of dynamic spectra under external perturbations such as temperature, concentration and changes in pH prior to analysis. After the spectral data have been obtained, the order of the spectral peak changes during metal-DOM binding (i.e., synchronous and asynchronous maps) can be shown by two 2-D plots (synchronous and asynchronous plots) (Cui et al., 2020). The 2D-COS offers the capability to perform heterospectral correlation analysis between different spectroscopic probes, and it complements the power of each spectroscopic probe and overcomes the limitations of using a single spectroscopic technique alone. For example, Zhu et al. (2018) found that humic-like components played an important role in the binding process of DOM and atrazine under four types of land use. The 2D-COS further confirmed that humic-like components combined first with atrazine followed by the protein-like components.

Laser induced fluorescence spectroscopy

Laser induced fluorescence spectroscopy (LIFS) formed by the absorption of fluorescence emitted when a molecule of a fluorescent substance absorbs laser energy to transition from the ground state to an excited state and back to the ground state. The main advantages of laser excited samples over lamp induced fluorescence spectra are the brightness, strong direction, monochromaticity and coherence of the laser excited radiation, resulting in a better signal-to-noise ratio and greater excitation selectivity, reducing factors that interfere with the fluorescence signal. Moreover, the use of a high- power laser source improves the sensitivity and can be applied to the determination of whole soil organic components (Tadini et al., 2021).

Fig. 3 Schematic diagram of a fluorescence correlation spectroscopy device and principle. Adapted from Martínez-Moro M, Di Silvio D, Moya SE (2019) Fluorescence correlation spectroscopy as a tool for the study of the intracellular dynamics and biological fate of protein corona. *Biophysical Chemistry* **253**: 106218.

Given that LIFS enables a faster evaluation of the quality and stability of soil organic matter (SOM), this technique has the advantage that it can be applied to whole soil samples without the need for laborious pretreatments. Furthermore, LIFS can be used to investigate in situ the degree of humification of intact SOM in untreated solid soil samples, which is feasible for the following reasons. First, excitation by near UV blue radiation is more likely to resonate with rigid systems containing condensed and/or substituted aromatic rings, which are conjugated to large π -electron systems that can emit fluorescent signals even when the sample is in a solid state. Second, a novel humification index (H_{LIFS}), corresponding to the ratio of the area under the broad emission-mode LIFS and the corresponding total soil C concentration measured by a conventional method, was proposed to evaluate the humification status of SOM assuming that the concentration of these systems increases with progressing humification.

X-ray fluorescence spectroscopy

In general, X-ray fluorescence spectroscopy is a versatile analytical technique that provides information on both qualitative and quantitative chemical elements. Electrons exist in atoms at discrete energy levels that are unique for each element. X-ray fluorescence occurs when a sample is illuminated by X-ray resulting in the ionization of its elements by the ejection of inner shell electrons. Subsequently, higher energy electrons transition to lower energy states and fill the voids in inner electron shells yielding either X-ray fluorescence or auger electrons. Auger electrons are generated when the X-ray fluorescence of an atom is re-absorbed by the outer electrons of the emitting element itself, and this effect dominates for lighter elements with lower atomic numbers. Due to the conservation of energy, electrons undergoing transition emit X-ray fluorescence that is unique to the atom. The X-ray fluorescence measurements are based on the entire contents of the analyte and volume of the matrix dependent fluorescence regression.

Time-resolved fluorescence spectroscopy

Time correlated single photon counting (TCSPC) was developed in the 1960s by Bollinger et al. The fluorescence intensity of molecules is directly proportional to the number of molecules in the excited state, and the decay rate of fluorescence intensity

reflects the residence time of molecules in the excited state. When molecules in the excited state have undergone processes such as chemical reactions or intermolecular energy transfer, the decay rate of the fluorescence intensity of molecules will change. Therefore, the study of fluorescence intensity with time can provide information about the reaction kinetics such as the rate at which the reactant molecules react chemically in the excited state, the interaction between the reactant and quencher molecules, and the effect of solvent on the reaction. Since the advent of time-dependent single photon techniques, TRF spectroscopy has been widely applied to the mechanistic study of biochemical reactions in solution. Because of its excellent temporal resolution, good measurement accuracy and sensitivity, large dynamic range, and easy storage and processing of data, this technique has been widely used in many fields. Central to time correlated single photon counting is photon counting technology, which can be used with the detection of weak signals. Recently, many TRF spectroscopic methods, such as laser-induced nanosecond TRF spectroscopy, have been derived on this basis. It can be used to study the interaction between SOM and organic pollutants or metal ions.

Conclusion

Fluorescence spectroscopy, including the emission, excitation, synchronous scan modes, total luminescence and 3D fluorescence, are noninvasive, nondestructive, and highly sensitive techniques that require minimal sample pretreatment. In addition, the unique properties of laser light sources have made LIFS a widely used method in SOM research. Therefore, fluorescence spectroscopy has broad application potential in the study of organic and inorganic soil components. For example, the diversity of inherent fluorescence structures in soil organic components, especially in their humified fractions, such as humic substances, mainly humic acids and fulvic acids, has provided invaluable information on their structural and functional chemistry and reactivity as a function of relevant environmental factors such as pH and ionic strength.

Abstract

Soil organic matter comprises typical light-absorbing or emitting structures and functional groups, and the source, optical properties and rotary motion of its molecules can be determined by the fluorescence method. A large variety of fluorescence technologies is applied to investigate the interaction process and related mechanism among soil organic components and chemicals from quantitative and molecular aspects. Static and dynamic fluorescence spectroscopy of organic probes sorbed on soil clay minerals can provide important and unique insights into the specific interface and surface behavior of soil mineral components, such as their molecular distribution, conformation, aggregation and mobility.

Key points

- The practical applications of fluorescence spectroscopy for soil organic matter and soil clay minerals are introduced.
- The interaction process and related mechanism among soil organic components and chemicals are investigated by fluorescence technologies.
- Specific interface and surface behavior of soil mineral components are explored by static and dynamic fluorescence spectroscopy.

Introduction

Fluorescence occurs when a singlet electron in the excited state is coupled with an electron in the ground state by opposing spins. Part I of this topic in the Encyclopedia gives the principles of the method. In this chapter, the practical applications of fluorescence spectroscopy for soil organic matter and soil clay minerals are introduced. For soil organic components and clay minerals, fluorescence spectroscopy can be applied to determine their structures, properties and the variation induced by environmental factors. To explore the interaction among chemicals and soil components, fluorescence quenching, polarization, correlation spectroscopy, and the excitation–emission matrix (EEM) and time resolved fluorescence are discussed.

Soil organic components

Fluorescence spectra

Soil organic matter (SOM) generally includes dissolved organic matter (DOM) and humic substances (HS). Its components are grouped according to their solubility into humic acids (HAs), fulvic acids (FAs) and humin. Humic acids are insoluble at pH < 2, whereas FA is soluble under both acidic and alkaline conditions. Humin is insoluble at any pH values. Soil organic matter comprises typical light-absorbing or emitting structures and functional groups which are susceptible to variations in ambient biochemical and geochemical conditions. Absorption and emission occur mostly from SOM with the lowest vibrational energy when the electronic energy levels of the fluorophores endure changes, which can be captured by optical spectra. Fluorescence spectroscopy has been widely exploited to explore the chemical composition and biogeochemical cycling of SOM because it is fast and sensitive. Therefore, it is an efficient tool to trace the sources, features and environmental behavior of SOM.

Steady-state and time resolved fluorescence (TRF) are the two main types of fluorescence method to measure HS. For example, steady-state fluorescence, the most common type, is performed with excitation, emission and synchronous fluorescence spectra and EEM fluorescence (Fig. 1) (Chen and Yu, 2021).

The SOM consists of various fluorescent structures, therefore, their fluorescence spectra contain diverse and interwoven fluorescence information. In the last two decades, many approaches have been developed to explicate the fluorescence data to decode the structural information of SOM. The EEM and synchronous fluorescence spectra are the main prevailing fluorescence approaches for investigating SOM. Synchronous fluorescence spectra are generally coupled with two-dimensional correlation spectroscopy (2D-COS) rather than EEM to simplify complex spectra with multiple overlapping peaks and improve spectral resolution. The EEM can be processed separately with sophisticated applications, such as fluorescence regional integration and parallel factor analysis, for a thorough separation of components and correction of data.

Steady-state fluorescence measurements are frequently applied to explore various spatial and temporal scales of DOM concentration, composition, and biogeochemical dynamics, and the time-resolved measurements are gaining attention because of their unique advantage. In general, most of the molecular information from fluorescence is lost by the time averaging process. For example, the shape of the anisotropic decay includes information on the conformation of the macromolecule and its flexibility, but part of that information is lost as the intensity decays over the decay time. Typically, macromolecules can have multiple conformations and the decay time of a binding probe may depend on the conformation. The intensity of decay can indicate different decay times as well as the existence of more than one conformational state. The steady-state intensity can only indicate a mean intensity based on a weighted mean of the multiple decay times. Furthermore, the intensity of decay could reveal how acceptors are distributed in space around the donors in the presence of energy transfer. Fluorescence quenching also expresses diffusion or complex formation with the ground-state fluorophores by time-resolved measurements. Thus, time-resolved measurement is essential for revealing molecular information, including the intermolecular clustering, conformational rearrangement of adsorbed polymers at the solid-liquid interface and changes in the advanced structure of proteins.

Nature of fluorophores

The fluorophores of SOM comprise assorted chemical groups, including carboxyl, phenol, quinonyl, aldehyde, ester, ketone, hydroxyl, amino, glycosyl and other functional groups. Because of the molecular complexity and chemical heterogeneity, fluorescence spectra of SOM probably represent the sum of the spectra of several different fluorophores. There is an urgent need for mathematical approaches that will separate and reasonably attribute each component of SOM due to its integral role in natural and engineered systems.

The 2D-COS method, first proposed by Noda in 1986, has become a routine analytical technique in spectroscopic studies. It has two main advantages, including enhancing spectral resolution and discerning relative directions and specific order of structural variations. The subtle key information can be evaluated from a variety of probes under various forms of external perturbations.

Fig. 2 Changes in the synchronous fluorescence spectra of 10 mg L^{-1} HA at pH 7.0 with the addition of copper at concentrations of 0, 1, 2, 5, 10, 20, 40, 60, 80, 100, 120 and $160 \times 10^{-6} \text{ mol L}^{-1}$ (a). Synchronous (b) and asynchronous (c) 2-D correlation maps generated from the synchronous fluorescence spectra of HA with increasing copper ion concentration in the 280–500 nm region. Adapted from Chen W, Habibul N, Liu XY, Sheng GP and Yu HQ (2015) FTIR and Synchronous fluorescence heterospectral two-dimensional correlation analyses on the binding characteristics of copper onto dissolved organic matter. *Environmental Science & Technology* **49** (4): 2052–2058.

In Fig. 2, HAs are regarded as a typical HS, and copper concentration was used as the external perturbation (Chen et al., 2015). The changes in the synchronous fluorescence spectra of HAs with the addition of copper, synchronous and asynchronous 2-D correlation maps generated from the synchronous fluorescence spectra of HAs with increasing copper ion were revealed in Fig. 2a–c, respectively. The 2D-COS, synchronous fluorescence and infrared absorption spectroscopy have been successfully combined to interpret the copper–DOM interaction mechanisms. It could reveal a sequence of heterogeneous binding sites in HAs and their subsequent subtle changes within the molecular interactions. The results showed that fluorescence quenching of fluorescent humic-like moieties occurred with a vibrational change of the related functionalities (i.e., phenolic and aryl carboxylic groups), which further induced the fluorescence quenching of fulvic-like fractions. Furthermore, small amounts of amide and aliphatic groups participated in the copper binding after fluorescence of the protein-like fraction decreased.

The EEM coupled with fluorescence regional integration (EEM-FRI) has been authenticated as a suitable method to integrate the volumes beneath defined EEM regions, making a semi-quantitative analysis of the configuration and heterogeneity of SOM. Fluorophores in SOM can be separated into five regions by FRI. Table 1 gives the excitation and emission wavelengths characteristic of each region (Chen et al., 2003). The EEM-FRI analysis can be used to trace the fate of SOM. But the application of EEM-FRI to evaluate SOM components is still controversial because the component concentration is not always linearly related to fluorescence intensity. In addition, interference might result in fluorescence quenching or enhancement of specific fluorophores in SOM, which might not be revealed by FRI.

The EEM combined with parallel factor (EEM-PARAFAC) analysis can convolute complex EEM fluorescence spectrum into independent fluorescent components that represent groups of similar fluorophores, which could help changes in SOM components to be comprehensively tracked. The EEM-PARAFAC analysis is non-destructive, but is valid only when the EEM data are trilinear (Table 2) (Ishii and Boyer, 2012). In addition, the EEM-PARAFAC technique provides only the information on finite components of SOM. Compared with EEM-PARAFAC analysis, EEM-FRI is a quantitative technique associated with all wavelength-dependent paired fluorescence intensity data in an EEM.

The effects of molecular and environmental factors on SOM

Changes in soil pH resulting from soil acidification can affect both the concentration and chemical characteristics of SOM. The extensive interactions with most inorganic and organic pollutants and SOM depend strongly on the protonation and complexation properties of SOM. Biological assimilation and degradation of organic carbon play a crucial role in regulating both the production

Table 1 Excitation and emission wavelength ranges of the five integrated regions identified by FRI.

FRI region	Excitation (nm)	Emission (nm)	Source
R1	200–250	250–330	Tyrosine-like protein
R2	200–250	330–350	Tryptophan-like protein
R3	200–250	350–500	Fulvic acid-like
R4	250–280	250–380	Microbial-like
R5	250–400	380–500	Humic-like

of greenhouse gases and accumulation and stabilization of SOM (Fig. 3). The DOM originates primarily from the decomposition of SOM that had accumulated from vegetation, the addition of biological materials (e.g., biosolids and livestock manures), the release of root exudates and the lysis of microorganisms (Bolan et al., 2011). Microbial degradation of SOM, followed by desorption of organic substances from the soil matrix are regarded as the most important processes that release DOM, and microbial assimilation of readily available carbon in DOM results in the ultimate degradation of DOM to carbon dioxide.

Fig. 3 Pathways of inputs and outputs of DOM in forest and agricultural soils. Fluorescent properties of soil dissolved organic components

Laboratory measurements and characterization of DOM for source identification and dynamic tracking have received much attention over the past two decades. The in-situ techniques providing optical properties to assess the quality of dissolved organic carbon (DOC) are sensitive, simple to use, precise, and non-invasive compared to chemical analyses. In general, fluorescent DOM signatures interpret specific spectral characteristics using a quantitative measurement of an ever-expanding number of optical parameters. These measurements are surrogates for the reactivity and composition of DOM. The intrinsic fluorescence optical parameters of DOM generally consisted of fluorescence index, humification index, freshness index, biological index and etc.

Fluorescence lifetime of soil dissolved organic components

Fluorescence lifetime can distinguish between static and dynamic quenching of fluorophores. For static quenching, the ratio, τ_0/τ , of fluorophore fluorescence lifetime in the absence (τ_0) and presence (τ) of a quencher is one. In contrast, the fluorescence lifetime of fluorophores for dynamic quenching depends on quencher concentrations; in this case, τ_0/τ is equal to the ratio, F_0/F , of fluorescence intensity in the absence (F_0) and presence (F) of a quencher (Table 3) (Fu et al., 2016).

Conformational studies by polarization

Fluorescence anisotropy was used to explore conformational variations in DOM and molecular interactions between it and environmental contaminants by evaluating the rotary motion of DOM molecules. Fluorescence intensity increased with rising HA concentrations between 20 mg L⁻¹ and 100 mg L⁻¹, while fluorescence polarization decreased. However, fluorescence intensity decreased and fluorescence polarization increased with HA concentrations >100 mg L⁻¹. This indicated self-absorption and collision related to fluorescence quenching and energy transfer. The HA was coiled in shape at concentrations of 20–100 mg L⁻¹ because of the variation in fluorescence polarization. But HA aggregated under higher concentrations (above 100 mg L⁻¹), resulting in prolonged planar conformation from strong repulsion between molecules. With increasing ionic strength of the solution, peak B of the HA decreased considerably, suggesting that conformational coiling occurred at Peak B (Fig. 4a) (Mei et al., 2009).

Fig. 4b shows that fluorescence polarization varied with pH. Neutralization of the molecular charge of the macromolecules of the HA resulted in agglomeration under acidic conditions. Nevertheless, for an individual molecule, the shortened molecular distance with agglomeration ultimately results in mutual repulsion between molecules and coiled molecular conformation. The increasing fluorescence polarization of HAs at lower pH (≤ 4) suggested that the formation of elongated linear conformation occurred in the HA macromolecules. As a result of protonation of carboxyl, molecular aggregation and repulsion led to elongated linear conformation of HAs.

Diffusion coefficients determined by fluorescence correlation spectroscopy

The properties of DOM are complex, heterogeneous and dynamic, and thus, it is important to reveal their effects on the spatial distribution of the dynamic information, such as concentrations, mobility, equilibrium, rate constants, and interactions related to the molecular size and weight of DOM. Fluorescence correlation spectroscopy (FCS) is one of few ultrasensitive and noninvasive single-molecule detection techniques for in-situ quantitative analysis. The average diffusion coefficients for Suwannee River FAs and Suwannee River HAs were determined by FCS in the range of $2\text{--}3 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ under different concentrations, hydration times, pH, and ionic strength (Ca^{2+} (calcium)) conditions, which corresponded to hydrodynamic diameters of approximately 1.5–2.1 nm. With a decrease of pH from 10 to 3, the slight but significant decrease in diffusion coefficients suggested that a little

aggregation occurs with the formation of dimers and trimers. Reduction in the diffusion coefficient was either small or insignificant with ionic strength changes up to 0.1 mol L^{-1} . There was no effect on FA and HA concentrations ($1\text{--}50 \text{ mg L}^{-1}$) or hydration time ($1\text{--}14$ days).

Fluorescence quenching of soil organic components by metal ions

Molecular and mechanistic aspects

Soil organic matter interacts with other chemicals, such as ‘heavy metal’ cations, in the natural environment to form complexes. Paramagnetic transition metal ions, such as Cu^{2+} (copper), Fe^{3+} (iron), Fe^{2+} , Ni^{2+} (nickel), Cr^{3+} (chromium) and VO_2^{2+} (vanadium), can effectively quench the fluorescence of HS by enhancing the rate of some nonradiative processes that compete with fluorescence, such as intersystem crossing. Cations such as Cd^{2+} (cadmium), K^+ (potassium), Na^+ (sodium), Ca^{2+} , and Ba^{2+} (barium) show no quenching effect. Metal ions and HS can form two main types of complexes: (1) inner-sphere and (2) outer-sphere. The quenching ability of Cu^{2+} on FAs is excellent, because the FAs formed strong inner-sphere complexes. This phenomenon binds several weak sites causing conformational changes that make available additional internal binding sites of FAs. On the contrary, outer-sphere complexes are formed by Mn^{2+} (manganese), and FAs that are not involved in weakly acidic phenolic sites where the ions are further away from the fluorophore.

The shifts in the optimal fluorescence emission or excitation peak often occur with interaction between HS and paramagnetic metal ions. The molecular nature or quality of soil organic components can influence their binding with cations. The fluorescence quenching of FAs by Mn^{2+} decreased with the increase in FA molecular weight. Synchronous fluorescence analysis of three molecular weight (MW) fractions of FAs shows that affinity of the large-MW fraction to Al^{3+} (aluminium) and UO_2^{2+} (uranyl) is larger than that of the small-MW fraction. The complexing ability of SOM and metal ions is highly dependent on pH values. The conditional stability constants (K_c) between lanthanides (14 elements) and HAs increased with increasing pH. Fluorescence quenching of HAs and FAs from various origins by Cu^{2+} , Co^{2+} (cobalt), Pb^{2+} (plumbum), Ni^{2+} and Mn^{2+} increases as pH increases.

Synchronous-scan fluorescence spectra, EEM-PARAFAC analysis and TRF have been used successfully to study the fluorescence quenching of FAs by metal ions. Principal component analysis of synchronous quenching spectra obtained by the difference between before-and-after additions of Cu^{2+} , Pb^{2+} , Ni^{2+} , Co^{2+} , Mn^{2+} , Mg^{2+} (magnesium), and Al^{3+} at various total concentrations indicates that multiple fluorescent binding sites of FAs are involved in divalent metal complexation in solutions at pH 7.5, but not pH 5.0. The Al^{3+} and Cu^{2+} ions compete for FA binding sites and displace Mg^{2+} bound to FAs. Synchronous fluorescence spectra usually have overlapping fluorophores, therefore, a method with better resolution is required to obtain accurate binding parameters. The EEM-PARAFAC analysis can be a reliable tool for determining binding parameters between metal ions and individual components within SOM.

The fluorescence score of all components in SOM decreased with Pb^{2+} more significantly than with Cd^{2+} , indicating the stronger interaction of SOM with Pb^{2+} than Cd^{2+} . It is possible to study organic matter–metal interaction with TRF because different chemicals have different fluorescence lifetimes, especially in complex samples like HAs. The results of TRF for the interaction between Cu^{2+} and HAs have shown that the average lifetime of HAs appears to be independent of Cu^{2+} addition, suggesting that the main interaction mechanism is static quenching with a non-fluorescent ground-state complex formation. Dynamic quenching, caused by the collision of a quencher that occurs during the lifetime of the excited state, affects the fluorescence lifetime of SOM. Static quenching occurs when a ground-state non-fluorescent complex is formed, and the fluorescence lifetime of a fluorescent ligand and complex are unaffected.

Quantitative aspects

Fluorescence quenching titrations of a soil FA with Cu^{2+} showed a complexing capacity (C_L) value of FA $\sim 20 \text{ mol L}^{-1} \text{ Cu}^{2+}$ at pH 6.0 and 7.0, and a K_c of the complex FA– Cu^{2+} two to three times greater at pH 7.0 than at pH 5.0 and 6.0. Average C_L and conditional stability constant (K_b) values determined by fluorescence quenching are of the same order of magnitude as those determined by polarographic titration. At pH 7.0 and 6.0 the final fluorescence intensity is approximately 20% of the initial value for FAs, and is 40% at pH 5.0, indicating that most FA fluorophores are directly involved in Cu^{2+} complexation.

The integral standard volume of the total fluorescence area ($\Phi_{T,n}$, $\text{au}\cdot\text{nm}^2$) values caused by different metals followed the sequence $\text{Cu}^{2+} > \text{Fe}^{3+} > \text{Cd}^{2+} > \text{Cr}^{3+} > \text{Zn}^{2+}$ (Fig. 5), indicating that they had different binding ability or reactivity with fluorescence SOM (Liu and Lang, 2021). The $\Phi_{T,n}$ of fluorescence DOM induced by Cr^{3+} and Zn^{2+} were much lower than those by Cu^{2+} and Fe^{3+} , indicating that fluorescent DOM has low binding ability to Cr^{3+} and Zn^{2+} . In addition, different fluorescence regions have different responses to metals (Fig. 5b). Specifically, about 33% humic-like and 21% aromatic protein II are involved in the binding between Fe^{3+} and DOM, indicating that humic- and protein-like substances play a key role in DOM– Fe^{3+} binding. In the binding of DOM and Cu^{2+} , humic-, fulvic-, and soluble microbial by product-like substances all exhibit a strong reactivity, accounting for about 35%, 24% and 21% of Cu^{2+} binding sites, respectively. However, Cr^{3+} showed different binding preferences, with fulvic-like substances contributing up to 35% of binding sites. In addition, humic-like substances are also important in Cr^{3+} binding, accounting for 26% of binding sites. In contrast, Cd^{2+} and Zn^{2+} mainly bind to protein-like components of DOM; protein-like I and II components accounted for 22% and 45% in DOM– Cd^{2+} binding and 38% and 22% in the DOM– Zn^{2+} binding respectively.

Synchronous-scan fluorescence spectra of FAs with increasing amounts of added Be^{2+} (beryllium) at pH ranged from 4.0 to 7.0, indicating a fluorescent component unaffected by Be^{2+} and another component resulting from the formation of relatively strong fluorescent complexes with Be^{2+} by different FA binding sites. The C_L values calculated are smaller at pH 4.0 than at higher pH values because of protonation of some FA binding sites that become unavailable to complexation at low pH. The K_b values were also increased from pH 4.0 to 6.0, but decreased slightly at pH 7.0. A similar analysis was applied to complexation of Cu^{2+} , UO_2^{2+} and Al^{3+} by FAs at various pH and concentrations. For Al^{3+} , one component corresponded to the formation of a fluorescent complex and another to a non-fluorescent complex. The K_b values indicated that the stability of FA– Al^{3+} complexes decrease markedly at pH < 4.5.

With increasing Al^{3+} concentration, fluorescence polarization increases for the smallest MW fraction of a soil FA and decreases for the largest MW fractions, suggesting that the former FA fraction does not change, whereas the latter fractions change conformation on complexation with Al^{3+} ions. The K_b values for Al^{3+} –FA complexes can be calculated with anisotropy values obtained from polarization data. Time-resolved laser fluorescence spectroscopy has also been used to calculate K_b values of complexes formed by soil HAs with trivalent metal ions such as Cm^{3+} (curium) and Eu^{3+} (europium).

Fig. 5 Integrated standard volume of the total fluorescence area ($\text{au}\cdot\text{nm}^2$) of ∇EEM (a), and the percentage contribution of different regions in ∇EEM (b). The concentration of all the metal ions is $10 \mu\text{mol L}^{-1}$ and that of dissolved organic carbon is 8.52 mg L^{-1} . Adapted from Liu MX and Lang YC (2021) Differences in the spectroscopic characteristics of wetland dissolved organic matter binding with Fe^{3+} , Cu^{2+} , Cd^{2+} , Cr^{3+} and Zn^{2+} . *Science of the Total Environment* **800**: 149476.

In general, fluorescence spectroscopy based on metal–HS complexation fluorescence quenching is more sensitive than anodic stripping voltammetry (ASV) and ion-selective electrode potentiometry (ISE) is sufficient for application to unmodified natural organic ligands without pre-concentration. Although several limitations and assumptions are inherent to fluorescence data analysis, this method has several advantages because it is relatively rapid and less sample is needed. Moreover, there is no need to add supporting electrolyte or buffer or adsorbing material to the sample, neither CO₂ nor O₂ interferes with the measurement, and its sensitivity is adequate. Thus, the errors associated with the separation step in most speciation methods are avoided. It also allows direct measurement of the complexing capacity of the ligand by determining the concentration of free ligands to distinguish between free and bound ligands.

Sorption or binding of fluorescent organic pollutants to soil organic components

Both fluorescence polarization and fluorescence quenching methods can be applied to molecular and quantitative studies of the binding or sorption of polycyclic aromatic hydrocarbons (PAHs) to soil organic components, and especially to HS. The major advantage of these methods is that no separation step is required, which eliminates possible errors due to incomplete separation of the free or dissolved from bound or sorbed pollutant with potential improvements in reproducibility. These methods are also relatively rapid and convenient, as well as offering good precision and inherent sensitivity.

Fluorescence polarization

Fluorescence polarization is preferentially applied where the pollutant molecule is an efficient fluorophore with respect to the adsorbent, i.e., the HS molecule. Alternatively, fluorescence quenching can be applied to systems where fluorescence of the pollutant is affected by that of HS. The fluorescence of perylene (Pery) in glycerol-water (75/25, w/w) solutions at pH values of 2.0, 5.0, and 11.0 becomes more polarized as a function of added FAs, which indicates that Pery binds to FAs, forming a larger species that rotates more slowly in solution than does Pery alone. Fluorescence polarization can be extended to non-fluorescent compounds by measuring either changes in intrinsic fluorescence polarization of the adsorbent HS molecule or with competitive binding experiments using an adequate fluorophore probe. In the first case, the polarization changes are likely to be small and difficult to measure with precision, thus good-quality instrumentation is required, whereas in the second case, irreversible binding and slow kinetics can complicate the experiment.

Fluorescence quenching

Fluorescence quenching is a sensitive and fast method to quantify the interactions between PAHs and a quencher, such as HS. The PAHs possess strong intrinsic fluorescence due to their conjugated structure, but its fluorescence intensity would be quenched when they are bound to HS. Thus, the binding characteristics of PAHs and HS can be obtained. Stationary combined with time-resolved measurements could be used to distinguish between static and dynamic quenching. Disregarding dynamic quenching may lead to an erroneous estimate of K_{oc} (adsorption coefficients normalized with respect to organic carbon content) values of the pollutants investigated, because of large contributions of dynamic quenching in some of the systems that require attention. For example, the HAs are chemically modified by bleaching, acid hydrolysis, and decarboxylation, and then used in fluorescence quenching experiments for phenanthrene (Phe), 9-phenanthrol (Ptr) and naphthalene (Nap). The quenching mechanisms of these chemicals depend on HA properties, aromatic components exhibit static quenching for Phe and Nap, while carboxyl groups dominantly display dynamic quenching. Aromatic components and carbohydrates in HAs primarily bind (static quenching) rather than collide (dynamic quenching) with Ptr. Carboxyl groups interact with Ptr by dynamic quenching only when carboxyl groups are on the benzene ring (Fig. 6) (Wang et al., 2017). Combining fluorescence quenching and dialysis equilibrium systems, enables exact quantification of the contribution of dynamic quenching. Dynamic quenching plays an essential role, its contribution is generally over 20%, and up to 95% for Nap. Interactions between Ptr and HAs have linear Stern–Volmer plots, and the contribution of dynamic quenching is over 60%. The quenching process should not be judged only according to Stern–Volmer equation (F_0/F vs. [DOC]) because a linear Stern–Volmer plot reflects a solely dynamic or static quenching, without any combination.

Chrysene (Chry) can bind to HAs by quenching the intrinsic fluorescence, and consequently the fluorescence intensity of HAs decreases regularly with the addition of Chry (Fig. 7) (Wu et al., 2020). The quenching rate constant (K_q) is $4.12 \times 10^{12} \text{ L mol}^{-1} \text{ s}^{-1}$ is greater than the collision quenching constant of $2.0 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$, showing that the process is static quenching.

The 2D-COS can be applied to analyze further the interaction between HAs and benzo[ghi]perylene (B[ghi]P). Although the synchronous spectrum cannot extract information on the HAs from the mixture, their fluorescence characteristics with smaller concentrations can be obtained from a sliced asynchronous spectrum at the signature peak of B[ghi]P (Fig. 8) (Xia et al., 2020). It demonstrates a novel approach for the separation of fluorescence intensities of HAs from PAHs, providing corrected spectra of PAHs for quantitative analysis of the mixture.

The conventional fluorescence quenching method depends on the emission spectral data of PAHs with single wavelength excitation. Nevertheless, in a natural environment where a variety of PAHs coexist, this technique cannot differentiate the interaction of a single PAH with HS from the overall fluorescence spectral information when measuring the binding characteristics

Fig. 6 Schematic diagram of HA-functional groups interaction with different chemicals. Fig. 8 Asynchronous 2–D correlation fluorescence spectrum of the low-concentration HAs and B[ghi]P mixture. Adapted from Xia MM, Dong GM, and Yang RJ (2020) Study on fluorescence interaction between humic acid and PAHs based on two-dimensional correlation spectroscopy. *Journal of Molecular Structure* **1217**: 128428.

Fig. 9 Three-dimensional fluorescence contour map of HA (a), and the Chry-HA system (b). Adapted from Wu JB, Geng B, and Sun XK (2020) Study on the interaction between chrysene with humic acids using fluorescence spectroscopy. *Polycyclic Aromatic Compounds* **40**: 960–966.

of HS to PAHs. Fortunately, EEM fluorescence spectroscopy provides this potential. For example, with the addition of Chry, the EEM fluorescence intensity of HAs clearly decreases (Fig. 9), suggesting that Chry could enter hydrophobic cavities in some domains of HAs, and the binding of Chry would induce some micro-environmental changes in HAs (Wu et al., 2020).

The EEM-PARAFAC analysis provides a detailed characterization of the binding process of PAHs and FAs (Fig. 10) (Lu et al., 2013). The K_c and binding capacities (L_t) of each PAH with FAs in a mixture can be calculated simultaneously by (Eq. 1). Log K_c is 2.78 for Flu and 2.44 for Ant, and L_t $8.65 \times 10^{-3} \text{ g L}^{-1}$ for Flu and $12.67 \times 10^{-3} \text{ g L}^{-1}$ for Ant, suggesting both PAHs bind tightly to FAs, thus increasing their solubility in water.

$$\frac{I}{I_{\text{ref}}} = 1 + \left(\frac{I_{\text{PF}}}{I_{\text{ref}}} - 1 \right) \frac{1}{2K_c L_t} \left[1 + K_c L_t + K_c C_F - \sqrt{(1 + K_c L_t + K_c C_F)^2 - K_c^2 L_t C_F} \right] \quad (1)$$

where I is the fluorescence intensity at a given C_F , I_{ref} is the initial fluorescence intensity of the PAHs without the addition of FAs, I_{PF} is the relative fluorescence intensity of the FAs-PAHs complex and K_c is the conditional stability constant.

Fluorescence quenching and synchronous-scan fluorescence spectroscopy has been used to obtain K_c for the binding of carbamate pesticides to soil DOM and HAs. For example, the binding constant of carbofuran is greater than that of carbaryl and aldicarb at pH 6.0. These results can be used to predict the potential transport of pesticides down the soil profile.

Soil mineral components

Static and dynamic fluorescence of organic probes can yield important and unique information about specific interface and surface behavior of clay particles in diluted colloidal dispersions or suspensions. The use of fluorescent probes is based mainly on their fluorophores, and the wavelength and time resolution are determined by the spectral properties of the fluorophores. Therefore, the lifetime of the fluorophores must be compared with the timescale of interest in the experiment. Intrinsic and external fluorophores constitute the two main categories of fluorophores. To obtain the relevant information required by the experiment, appropriate fluorescent probes should be selected. For example, the measurement of pH can be carried out with a pH sensitive fluorescent probe. Moreover, the influence of background fluorescence must also be considered when determining the target substances in soil.

To measure properties of soil mineral material, the commonly used fluorescent probes include some organic cationic dyes, such as acridine orange (AO), methylene blue, proflavine and rhodamine 6G, and various PAHs, such as Ant, 1,2,5,6-dibenzoanthracene, Pery, B[a]P, pyrene (Pyr) and various cationic pyrenyl derivatives. Advantages of the fluorescence methods to determine mineral components in soil are as follows: (1) it has great potential for non-invasive research of colloidal suspensions because there is no need for a complex pretreatment process for solid-liquid separation; (2) the specific fluorescent probe can detect very small concentration targets in hydrated clay suspensions under natural environmental conditions because of the analytical sensitivity of the fluorescence method; (3) the fluorescent probe detection signal not only provides information about target detection substances, but can also provide multi angle information of the colloid solution surface; (4) reaction rates can be determined continuously across wide time scales, ranging from minutes to femtoseconds. In addition to the reaction rates, events occurring at femtoseconds can be measured by TRF decay.

There are still some disadvantages, however, in using fluorescence spectroscopy to study mineral systems that need to be solved. First, dense colloidal solutions can lead to excessive light scattering, which is not conducive to the excitation and recording of the fluorescence signal. Second, fluorescence quenching also affects the collection of fluorescence signals. For example, the Fe^{3+} ion is located within the crystal structure or on the surface of clay minerals, and it can exchange electrons with the fluorescence probe to cause fluorescence quenching. Therefore, the use of fluorescence is restricted by the concentration of the suspended colloidal solution and the cations that may produce a quenching effect.

Fig. 10 The EEM fluorescence spectra of FA (a), fluorene (b), and anthracene (c) generated by PARAFAC analysis. Adapted from Lu R, Sheng GP, and Liang Y (2013) Characterizing the interactions between polycyclic aromatic hydrocarbons and fulvic acids in water. *Environmental Science and Pollution Research* **20**: 2220–2225.

Structural quenching

The quenching effect of fluorescent probes tris (2,2''-bipyridyl) Ru^{3+} (ruthenium) and tris (2,2''-bipyridyl) Cr^{3+} on sodium saturated Wyoming montmorillonite is better than that on synthetic montmorillonite containing Cr^{3+} in the octahedral layer. Furthermore, compared with the Fe^{3+} and Cr^{3+} in complex states, which means they are in octahedral positions, the Fe^{3+} and Cr^{3+} at the interlayer exchange sites are more likely to have electron exchange reactions with the fluorescence probe, that is, fluorescence quenching is more likely to occur. Similarly, the quenching efficiency of octahedral Cu^{2+} for the adsorbed fluorophore [4-(1-pyrenyl) butyl] trimethylammonium (PN4) is higher than that of exchangeable Cu^{2+} . These effects can be attributed to the close combination of adsorbed fluorine groups with siloxane dihedral cavities on the clay surface.

The accessibility of fluorophores to quenchers can be used to determine the position of fluorescent species at the mineral-water interface and its distribution in mineral micelles. For example, the inorganic fluorophore Ce^{3+} (cerium) preferentially occupies ion exchange sites in the tubules of imogolite. The site of solubilization of Pyr determines the mechanism of quenching by polar and non-polar quenchers. When the fluorescent probe Pyr is at the water-clay micelle interface, it is easily quenched by polar and nonpolar quenchers, but when it is inside the nonpolar micelle it will not be quenched by polar quenchers (such as Cu^{2+}). However, in both cases, the fluorescence of Pyr is easily quenched by non-polar quenchers, and the Pyr can also be dissolved within the interior of micelles.

Adsorption of organic chemicals to mineral surfaces

Measurements of anisotropy can reveal the average angular displacement of the fluorophore between photon absorption and subsequent emission. This angular displacement depends on the rate and degree of rotational diffusion in the lifetime of the excited state. The rate of rotational diffusion depends on the viscosity of the solvent and the size and shape of the rotating molecules. The rotational rate of fluorophores in solution depends on the viscous drag imposed by the solvent. A change in solvent viscosity will result in a change in fluorescence anisotropy. Therefore, the adsorption of Ant, Pyr, Pery, 1,2,5,6-dibenzo Ant, B[a]P and Chry on a hydrosol kaolinite was studied by the fluorescence polarization method. In all cases, fluorescence anisotropy decreased significantly as a function of PAH concentration, which means that the rotational relaxation time at low concentration is much larger than that at high concentration. The change in fluorescence anisotropy is clearly related to the concentration of colloidal kaolinite. At small concentrations, most PAH molecules are adsorbed on colloidal kaolinite, and their motion in solution is hindered. With increasing concentration, surface saturation of the colloid is reached, and additional molecules are no longer adsorbed and remain 'free' to rotate, leading to the decrease in fluorescence anisotropy.

Electro fluorescence polarization spectroscopy has also been used to measure the polarization of aqueous suspensions of the clay minerals sepiolite, attapulgite and saponite particles. These aqueous suspensions are labeled with dye molecules of different sizes and charges, and oriented via the application of an electric field. The data obtained make it possible to infer different possible binding sites between the dyes and clay. For example, cationic dyes are mainly confined to the channel of sepiolite rods, while attapulgite or Hector stone has no effect on them. To analyze the fluorescence information obtained fully, EEM-PARAFAC can be used to examine the chemical interactions between soil mineral surfaces and DOM. For example, the PARAFAC of multidimensional fluorescence spectra enables direct determination of the different affinities of the modeled DOM components (i.e., fluorophores) to soil mineral surfaces. This information may be a valuable management tool in assessing the potential sequestration of organic matter derived from a variety of carbon-rich soil amendments in both managed and unmanaged ecosystems.

The fluorescence results showed that DOC desorbed from mineral soil surfaces had a substantially lower fluorescence index than the equilibrium DOC solution. This finding also emphasizes the need to be aware that while overall DOC concentration may reduce substantially, the resulting composition of DOC in the solution phase can reflect not only adsorption, but also desorption processes. Based on the fluorescence index, soils with the greatest capacity to adsorb DOC had the greatest decrease in molecular weight distribution and aromatic content. From an ecological perspective, the Fe status of mineral horizons may be of primary importance when attempting to predict the quantity and quality of DOC exported from soils into aquatic ecosystems. In summary, fluorescence polarization can be used to study the interaction between organic pollutants and natural minerals without any separation. The dependence of fluorescence anisotropy on fluorophore motion has resulted in applications of this technique to dynamic processes such as temperature effect and clay adsorption on the properties of fluorophore.

Surface acidity

In addition to the interaction between a fluorophore and the surrounding environment, the fluorophore can also undergo chemical excitation, because the distribution of electrons in the fluorophore is changed by light absorption, thus changing its chemical or physical properties. For example, phenol and naphthol can lose phenolic protons in an excited state in a neutral solution. Because deprotonation is more likely to occur in the excited state, electrons from the hydroxyl group are likely to be transferred to the aromatic ring, making the solution more acidic. Therefore, fluorophores with pH-dependent fluorescence can be used to detect the acidity of a clay surface and the protonation of organic molecules at the clay-solution interface. For example, the emission spectrum of quinoline on sodium saponite shows that quinoline ions are adsorbed on the surface in the range of pH 3.0–9.0. The protonation of quinoline can be attributed to the specific acidic sites at the mineral-water interface and the strong ion exchange capacity of quinoline ions. In addition, the characteristic emission spectra of diprotonated protoflavine were observed when sodium saturated montmorillonite, Wyoming bentonite or saponite suspension was added in a monoprotonated form.

Whether a fluorophore loses or gains a photon, in the excited-state reaction is determined from the direction of change in the acid dissociation constant (pK_A). If the pK_A decreases ($\text{pK}_\text{A}^* < \text{pK}_\text{A}$), where the asterisk denotes the excited state, then the fluorophore will tend to lose a proton. If the pK_A increases ($\text{pK}_\text{A}^* > \text{pK}_\text{A}$), then the fluorophore may obtain a proton in the excited state. Based on this process, fluorescence spectra can be used to infer the presence of both protonated and unprotonated species on the clay surface. For example, aminopyrene sorbed to colloidal silica exhibits both the largely structured emission spectrum of protonated aminopyrene and the broad, featureless emission of neutral aminopyrene, which indicate the presence of both species on the surface; the protonated one on the more acidic sites, and the neutral one on the less acidic sites.

Fig. 11 (a) pH dependent fluorescence of PCN-225 in aqueous solutions with pH ranging from 0 to 10.2 measured under excitation of 415 nm. (b) Blue points showed fluorescence emission at 725 nm at different pH values, matching the simulation fluorescence intensity (red line), and (c) protonation and deprotonation processes of porphyrin involved in the PCN-225 framework of experimental acidic and basic media (pH = 0 to 10.2). Adapted from Jiang HL et al. (2013) An exceptionally stable, porphyrinic Zr metal-organic framework exhibiting pH-dependent fluorescence. *Journal of the American Chemical Society* **135**(37): 13934–13938.

Based on these pH-related properties, relevant fluorescent sensor materials can be developed, zirconium–porphyrin frameworks, PCN-225 and PCN-225(Zn), have been developed as the first metal–organic framework (MOF) with a (4,8)-connected SQC net.

They exhibit strong chemical stability in aqueous solutions with pH values from 1.0 to 11.0 (Fig. 11), and as far as we know, this is the most extensive pH range at which porphyrin MOF can exist (Jiang et al., 2013). It is worth noting that PCN-225 has stability at a wide range of pH. With the change of pH, the central core region of a porphyrin free base is in the equilibrium state of protonation and deprotonation, and its fluorescence intensity is closely related to the change of pH; $7.0 < \text{pH} < 10.0$ is the most sensitive range for intensity response. The results show that PCN-225 has broad application potential for pH sensing. In addition, the ready-made installation of the metal sites exposed by the porphyrin center in PCN-225, coupled with its stability, should improve its potential in various application fields, especially catalysis, light acquisition, sensors, and so on.

Polarity and charge adsorption of mineral surfaces

Research has shown that some fluorescent probes have great sensitivity to the polarity of the surrounding solvent, therefore, these probes can provide specific information about the charged regions on colloidal mineral surfaces. The large value of the ratio of

fluorescence emission intensities at $\lambda = 372$ to $\lambda = 391$ nm (I/III ratio) of Pyr, [3-(1-pyrenyl) propyl] trimethyl ammonium (PN3), and 8-(1-pyrenyl) octyl ammonium (PN8), adsorbed on to laponite from water and methanol solutions, confirms that the charged regions of the interlamellar surfaces of clay particles are largely polar. In contrast, the very small I/III ratios observed when fluorescent probes are adsorbed on to clays coated with alkylammonium surfactants, suggests that they are in less polar environments in forms strongly associated with the adsorbed surfactants.

Organic dye molecules can also alter the apparent polarity of clay mineral surfaces. Cationic dye molecules can exchange ions at permanent charge sites on the internal and external surfaces of mineral as well as at acidic sites on the mineral edges. For the fluorescence measurements, powdered samples were placed on quartz substrates. Fluorescence was excited by a continuous wave He–Cd laser at 325 nm. Klika et al. (2009) have confirmed that a small layer charge and small amount of adsorbed methyl blue (MB) induce large fluorescence intensities in MB after laser excitation. They found that the reduced charge of montmorillonite with loading a small amount of MB had large fluorescence intensity after laser excitation. A single sharp fluorescence maximum of these complexes matches the presence of dye monomers attached to the montmorillonite surface. The charge of the silicate layer had a strong effect on the peak shift of the crystalline methyl red (MR) fluorescence band. When MR is adsorbed on montmorillonite and vermiculite, the maximum shift of the fluorescence band is transferred from 800 nm to 565 nm and 645 nm, respectively.

Molecular distribution, conformation, aggregation and mobility

Excitation spectra and fluorescence lifetime measurements show that adsorbed cationic probes, including PN4, PN3, and PN8, tend to cluster on the surfaces of hydrated clay minerals, and then form fluorescent dimers like excimers. By analyzing the ratio of monomer emission to excimer emission of Pyr-labeled polyacrylic acid (Pyr-PAA) in solution and the ratio of adsorption to aluminium oxide in aqueous suspension, the effect of pH on the interfacial conformations of polymeric and polyelectrolyte macromolecules (e.g., Pyr-PAA) can be examined. No change in excimer emission intensity is observed: when Pyr-PAA is adsorbed on to aluminium oxide at pH 8.0, the solid is separated from the aqueous phase and then resuspended in a solution at pH 4.8. This result shows that the polymer is adsorbed in the uncoiled, linear conformation and remains uncoiled independent of the pH of the surrounding medium. In other words, no conformation change occurs as a function of pH. In contrast, excimer emission intensity is observed to decrease when Pyr-PAA is adsorbed on to aluminium oxide at pH 4.7; the particles are separated and then resuspended at pH 8.0.

The formation of dye aggregates is affected by the charge density. The higher aggregates (H-aggregates) with a face-to-face association of dye cations would be formed on high charge-density surfaces, while monomers, dimers, and less densely packed conjugated polymers were favored over H-aggregates with a moderate reduction in layer charge. The dye is positively charged and minerals overall are negatively charged. Although the lumen of halloysite is positively charged, it is unlikely that hydrophobic interactions between acridine orange (AO) and the charged mineral surface played a role. The oxygen on the surface of the tetrahedral sheet has strong electronegativity and thus, could interact with AO^+ . Substitution of Al^{3+} for Si^{4+} (silicon) at tetrahedral sites could also contribute to the net negative surface charge, seat of charge, and charge density of the minerals, which could cause the sorption and aggregation of AO on their surface. In addition, at maximum AO adsorption, the tight packing of AO leads to stronger intermolecular interactions, resulting in the formation of dimers and other aggregates, ultimately leading to significant fluorescence quenching. Interestingly, for the same mineral class, the adsorption, absorption, and strength of Cm^{3+} (curium) increase with surface roughness around the surface holes or grain boundaries.

Surface roughness becomes the main retention property of minerals with low adsorption capability when competitive adsorption occurs between multi-mineral phases. In high surface roughness areas primarily, Cm^{3+} inner-sphere sorption complexation and surface incorporation are prominent and at selected sites formation of stable Cm^{3+} ternary complexes is observed. The adsorption of organic matter by clay minerals in lake sediments plays an important role in organic matter burial. The clay surfaces selectively preserve algal organic matter (AOM) in eutrophic lakes, and the fraction of various AOM components preserved varies. Fluorescence emission spectroscopy has a promising future in studying the molecular structure of other polymer interfaces in the mineral–solution region. However, confirmation of fluorescence results usually requires the use of one or more additional techniques, such as molecular simulation.

Biochemical transformation of clay surfaces

Degradation of quinoline in a hectorite suspension by bacteria was studied by fluorescence spectroscopy. At pH values well above the logarithmic base dissociation constant (pK_b) of quinoline (4.9), the only fluorescent species was the protonated quinolinium ion adsorbed on to hectorite surfaces. During microbial degradation, the reduction in concentration of adsorbed quinolinium was monitored together with production of the metabolite 2-hydroxyquinoline. Desorption of the adsorbed quinoline ions was determined as the rate-limiting step in the bacterial degradation of quinoline by comparing the degradation rates of saponite with and without hectorite.

The interactions between microorganisms and clay minerals involve the formation, transformation, and preservation of organic matter formation. In addition, the bioavailability of 'heavy metals' is strongly influenced by the formation of clay mineral–bacteria complexes and their derivatives. Therefore, bacterial biomineralization is increasingly being considered as a good alternative for the remediation of contaminated soils, to recover the fertility of abandoned mining lands, and to precipitate or immobilize toxic metals. Bacterial biomineralization can also be used for the treatment of sewage, and industrial and domestic wastewater.

Ligand-promoted mineral dissolution

Direct evidence can be provided for the formation of fluorescent inner-sphere complexes between Al^{3+} ions and 8-hydroxyquinoline-5-sulfonate at the Al oxide-water interface. Fluorescence measurements show that concentration of the surface complex is constant during long-term dissolution of the oxide, which indicates that the oxide surface is continuously regenerated during dissolution; this confirms a surface-controlled process of mineral dissolution.

Previous studies have shown that organic ligands could significantly affect the kinetics and reaction mechanisms of mineral dissolution through surface complexation with metal ions. Fiore et al. (2011) found that kaolinite can be formed through a two-step biological induction process. The first step is precipitation of aluminosilicates in the presence of oxalates and other organic compounds, including extracellular polymers substances, which are metabolites produced by bacteria. The second step is due to micro-environmental changes caused by the metabolic activity of bacteria, and the gel may dissolve locally or rearrange into a kind of solid state, forming kaolinite crystals.

Conclusion

The practical applications of fluorescence quenching, fluorescence polarization, fluorescence correlation spectroscopy, EEM and time-resolved fluorescence can be applied to explore the interaction among soil components and chemicals. For example, fluorescence anisotropy was used to explore conformational variations in DOM and molecular interactions between it and environmental contaminants by evaluating the rotary motion of DOM molecules. Moreover, synchronous-scan fluorescence spectra, EEM-PARAFAC analysis and TRF have been used successfully to study the fluorescence quenching of FAs by metal ions. For the micro-environmental behavior of chemicals of the soil mineral components, the above techniques could not obtain valid information. To address this issue, further study should focus on the application of fluorescence imaging technology.

Abstract

Soil Infrared spectroscopy uses electromagnetic energy to characterize the soil. In the past decades, visible, near to mid infrared spectroscopy has gained considerable interest as a viable alternative for in-field and laboratory measurements, especially where a high spatial density of measurements is needed, because of its speed and cost-effectiveness. Once chemometric models have been calibrated, a single spectrum can be used to predict a range of soil properties simultaneously. This chapter provides an overview of spectroscopy in soil research, including predicting physical, chemical, and biological properties, as well as determination of soil contaminants.

Key points

- Infrared spectroscopy has been used to predict a range of physical, chemical and biological soil properties successfully.
- Soil contaminants have also been successfully quantified with infrared spectroscopy.
- Developments in artificial intelligence, computational power and big data have made more complex machine learning algorithms possible.
- Smaller, portable and lower-cost spectrometers are now available.

Introduction

Obtaining quantitative soil information rapidly and objectively is essential for monitoring current soil conditions and maintaining if not improving them, to ensure the current management practice does not lead to soil degradation. Quantitative soil data, which vary in time and space, are conventionally obtained from laboratory analysis. However, this is expensive, time-consuming, and requires the use of chemical reagents.

Research has been conducted worldwide to investigate proximal sensors that can measure soil properties from a close distance to the soil surface using a various range of wavelengths of the electromagnetic spectrum as shown in Fig. 1. The electromagnetic energy ranges from gamma rays which have higher frequencies to radio waves with the lowest frequencies. The interaction of energy with matter depends on its molecular composition. A material can reflect, scatter, or emit electromagnetic radiation, which results in a unique spectral signature. These sensors measure the response of the material at certain wavelengths, providing information about its constituents. Soil responds uniquely to the infrared spectrum, and the technology has made infrared spectrometers suitable for the analysis of soil samples as they can measure rapidly, cost-effectively, and non-destructively.

Spectroscopy in soil science

Optical sensors utilize various wavelengths from the electromagnetic spectrum (Fig. 1) to characterize properties (visible (vis): 400–700 nm; near-infrared (NIR): 700–2500 nm; mid-infrared (MIR): 2500–25,000 nm). The absorption in the MIR region can be readily identified as it is related to the fundamental vibrations of molecules. The absorbance in the vis–NIR is more difficult to

Fig. 1 The electromagnetic spectrum showing the boundaries between different regions, including the visible region (380–700 nm), the near infrared (NIR; 700–2500 nm), the mid-infrared (MIR: 2500–25,000 nm), and the far infrared (FIR 25,000–1,000,000 nm).

Fig. 2 The vis-NIR-MIR spectra of two soil samples showing fundamental peaks on MIR and overtones on NIR.

interpret as there are fewer and broader absorptions related to overtones and combinations of the fundamental vibrations in the MIR region. Absorptions in the visible region are associated with minerals that contain iron and organic matter, while absorptions in the NIR region (780–2500 nm) result from the overtones of hydroxyl (OH^-), sulfate (SO_4^{2-}), and carbonate (CO_3^{2-}) groups, and combinations of fundamental features of water (H_2O) and carbon dioxide (CO_2) (Stenberg et al., 2010). An illustration of spectra from the vis-NIR-MIR region is included in Fig. 2.

Discovery of the infrared region dates back to 1800 by Herschel (1800). However, the practical applications did not occur until 150 years later. In 1950s, researchers explored the use of infrared to characterize soil minerals (Hunt et al., 1950). In the 1980s, although NIR was mainly used in agriculture and the food industries, it became popular the decade after when practical applications started to expand to other industries, including pharmaceutical, earth science and environmental analyses. In soil science, early use of near infrared spectroscopy was by Bowers and Hanks (1965) where the influence of moisture, organic matter and particle size on the soil absorbance spectrum were observed.

Both vis-NIR and MIR have been used to determine successfully various chemical (pH, cation exchange capacity, carbon contents (organic, inorganic, and total) and nutrient contents), physical (texture (sand, silt and clay) and minerals (kaolinite, gibbsite, montmorillonite and iron oxides)), and biological (microbial biomass and enzyme activities) soil properties (Soriano-Disla et al., 2014).

The use of infrared spectroscopy is gaining interest for applications in various settings due to its possible application on different platforms, ranging from proximal sensing in the field, within the laboratory setting to remote sensing platforms with hyperspectral capabilities. Improvement in instrumentation also leads to the development of portable and handheld spectrometers. Recently, lower-cost portable and miniaturized NIR spectrometers with limited wavelength ranges have also become available, making it a cost-effective method of analysis for farmers, agricultural consultants, and researchers. It has been demonstrated that the miniaturized spectrometer provided comparable accuracy to the standard vis-NIR spectrometer (Tang et al., 2020).

Over the past two decades, the application of spectroscopy to complement soil analyses has increased rapidly. This increase is correlated with progress in the multivariate statistical data analysis and the development of both infrared and computer technologies.

Fundamental absorption of clay minerals

The vis–NIR and MIR spectra can be used for detecting clay mineral species and iron oxides. The most common soil forming clay minerals include kaolinite, montmorillonite (also commonly referred to as smectite) and illite. The most common iron oxide species include hematite and goethite. These minerals are distinct in composition, structural arrangements, and physicochemical characteristics. Consequently, each mineral has specific spectral responses at specific wavelengths in the electromagnetic spectrum (Clark et al., 1990). Earlier contributions from Gadsden (1975) comprehensively summarized diagnostic spectral features of minerals. Some diagnostic wavelengths in both the vis–NIR and MIR spectral regions for the key clay minerals and iron oxides are provided in Table 1.

The relatively simple way to assess the mineral composition of a soil sample directly from infrared spectra is to compare the reflectance of the diagnostic wavelengths from the reference spectra with those at the same wavelengths of the soil samples. As established, the wavelength ranges specifically diagnostic to each clay mineral and iron oxide specimen are known and they can be isolated and standardized by fitting a convex hull to them. The convex hull fits a straight line that connects the local maxima of the spectrum of a specific wavelength range and represents the background information. Fig. 3 shows an example of the fitted convex hulls to the diagnostic reflectance ranges from the reference spectra sourced from the United States Geological Survey (USGS) spectral library for end member specimens of smectite and kaolinite, and the associated spectra once the continuum is removed.

Soil infrared spectra are similarly standardized followed by the application of comparative metrics between reference and soil spectra to derive relative abundances. For example, shape match algorithms can be used and are implemented in the USGS Tetracorder decision making framework for mineral detection (Clark et al., 2003). Other metrics include relative area and depth of the absorbance feature and slope of the convex hull. Relative abundance of the minerals can then be inferred. For example, Fig. 4 provides statistical summaries of the relative abundances of kaolinite and smectite minerals derived from soil survey samples from the Hunter valley region, NSW Australia used in Malone et al. (2014). Here, there is a clear relationship between estimated abundance and its corresponding spectral response feature relative to the reference specimen.

The alternative to direct inference on mineral composition from infrared spectra is with soil spectral calibration models, which are described in more detail further on. Robinson and Kitching (2016) demonstrated this where partial least squares regression (PLSR) and support vector machine models were trialled and constructed to estimate soil clay mineral compositions (kaolinite, smectite and illite) based on associated soil MIR spectra. These models were extended to a larger spectral library to enable digital soil mapping of these variables in their study area in Victoria, Australia. The authors reported that their model can have an accuracy of 70% or better for each of the mineral species.

Soil chemometrics

As soil is a complex mixture of materials, it is difficult to assign particular features of the spectra to specific physical, chemical, or biological components. Multivariate calibration techniques are used to predict soil properties, relating the spectra to observed soil properties (properties that have been measured using conventional laboratory analysis).

Digital soil spectra usually contain hundreds or thousands of reflectance values as a function of wavelength. Since there are typically more predictor variables than the observed variables, methods that reduce the dimensions of the predictors are required. Principal component regression and PLSR are commonly utilized methods. Partial least squares regression extracts successive linear combinations of the predictors, optimizing the combined goals of explaining response variation and predictor variation.

Another way to handle large dimensional data is to use variable selection techniques. When the high dimensional data have been reduced to several components or important variables have been selected, they are used for prediction using either linear regression or data-mining tools. Regression trees, neural networks and support vector machines have been used for such predictions.

There are also machine learning algorithms that can handle a large dimension of inputs and extract information from many samples. Models such as Cubist models, random forest, neural networks, support vector machines have been trialled successfully for predicting soil properties from vis–NIR and MIR data. While such models have been used successfully for prediction, each model

Table 1 Diagnostic wavelength ranges of clay minerals and iron oxides as reported by Gadsden (1975).

Mineral	Diagnostic wavelength range(s) in wavenumber (cm^{-1})	
	Visible and near infrared	Mid infrared
Kaolinite	4812–4411	3636, 2710, 1923–1818, 1587, 1064, 855
Smectite	4721–4372	3636, 1961, 1852, 1639, 1111, 1064
Illite	4640–4413, 4336–4192	3226, 2874, 2141, 2604–2513, 1799, 1639
Goethite	21,881–17,761; 12,887–7899	912–882, 812–793
Hematite	21,978–16,340; 13,072–9524	560–550

Fig. 3 Diagnostic wavelength ranges for smectite and kaolinite. To prepare for analyses, spectra need to be standardized by fitting a convex hull (red line). Soil spectra and reference spectra are then compared based on the continuum removed spectra. Sourced from Malone BP, Hughes P, McBratney AB, Minasny B (2014) A model for the identification of terrons in the Lower Hunter Valley, Australia. *Geoderma Regional* 1: 31–47.

Fig. 4 Continuum removed soil spectra (dashed lines) with comparison to reference spectra at their given diagnostic wavelength ranges. The dashed lines represent (as numbered for kaolinite) the spectra for soils where relative mineral abundance is (1) the minimum, (2) first quartile, (3) second quartile, (4) third quartile, and (5) maximum. Partial figure sourced from Malone BP, Hughes P, McBratney AB, Minasny B (2014) A model for the identification of terrons in the Lower Hunter Valley, Australia. *Geoderma Regional* 1: 31–47.

form varies in complexity and ability of interpretation, and these features should be considered in detail in the exploratory stages of soil spectral model development.

Large soil spectral libraries are expanding as more spectral data are collected at a regional or national scale. An emerging method used for large data and the processing complex images, and which is capable of handling high-dimensional data is the deep learning model. One form is the convolutional neural network (CNN) which is widely used in handling high dimensional data, such as images. Ng et al. (2019) explored the use of the CNN model for predicting soil properties on a large vis-NIR and MIR spectral database. The architecture of the CNN model is quite flexible and can accept multi-dimensional input and provide multi-task predictions. The study reported that deep learning on an extensive MIR spectra library could predict fundamental soil properties (texture, organic and inorganic C, CEC, and pH) very accurately with $R^2 > 0.95$. Furthermore, only one model needed to be trained to provide predictions of multiple properties. Data fusion can also improve the prediction of soil properties.

Soil properties

Soil physical properties

Soil physical properties regulate the movement, retention and availability of water and nutrients to plants, and determine the flow of heat and air into, within and out of the soil. Despite the importance of these properties, a common feature in their measurement is that they often require considerable time to collect the data, are expensive to acquire, and require very specialized equipment. Consequently, alternative and less costly approaches with pedotransfer functions, which exploit easier to acquire attributes coupled with statistical modelling, have been proposed and have demonstrated their utility in numerous applications. Similarly, soil spectral modelling of these attributes has been demonstrated. Soriano-Disla et al. (2014) provide an all-encompassing review of the applicability of vis-NIR and MIR spectroscopy for the prediction of various soil properties such as texture, aggregation and soil water content. Stenberg et al. (2010) provide a similar account but focus specifically on vis-NIR soil spectroscopy. It is recommended that readers review those contributions and the references cited therein to appreciate not only the breadth and variation of studies that have been undertaken, but also the comparative assessment of their model performances.

In general, MIR spectroscopy outperforms vis-NIR for most soil physical properties. Soil spectral models based on properties like clay, sand and water content using either vis-NIR or MIR spectra are generally comparable ($R^2 = 0.7$ – 0.8). Soil aggregation as measured by wet sieving also been reported as being well-predicted, for example, mean aggregate diameter and mean weight diameter with R^2 values between 0.66 and 0.79. Despite seemingly good modelling outcomes reported for soil physical properties mentioned above, there are also corresponding examples where outcomes have not been so good such as bulk density and water retention at field capacity. There are many potential causes for this variability, with some stemming from the data used and the extent of soil variability captured, to differences in models and how the data are processed and handled. However, the more probable reason is that soil spectral calibrations of soil physical properties are really about the utilization of variables related to these properties that are known to be well-predicted, such as clay, soil carbon, and mineralogy. This co-relationship is acknowledged in the reporting of very good results in the prediction of COLE and Atterberg limits with vis-NIR spectroscopy and reported R^2 of 0.84 and 0.48–0.71, respectively (Rehman et al., 2020). Utilizing both soil spectroscopy and pedotransfer functions together, i.e. soil spectral inference (McBratney et al., 2006), is seen as a more appropriate way to estimate some soil physical properties, particularly those based on soil pore-space relationships, e.g. volumetric water retention, hydraulic conductivity and penetration resistance, and bulk density. This somewhat echoes the conclusions from Minasny et al. (2008) that soil physical properties based on soil pore space relations are not in general well predicted directly with infrared spectroscopy, therefore more focus should be given to soil spectral inference systems to improve what can be predicted well and use those estimates in existing or, newly calibrated pedotransfer functions.

Soil chemical properties

Near- and mid-infrared spectroscopy is mostly used to predict soil chemical attributes. These properties affect soil biological activity and nutrient dynamics in the soil and have been used as soil quality assessment indicators. Soil chemical properties include pH, organic carbon, nitrogen, nutrients, as well as cation exchange capacity.

Numerous studies had been carried out to measure soil carbon. This interest is due to the recognition that storing additional carbon in the soil serves as one of the options to mitigate anthropogenic climate change. Soil organic carbon is a component of soil organic matter that affects the physical, chemical, and biological properties of soil, influencing soil structure, water and nutrient retention. In addition to total carbon, organic and inorganic soil carbon predictions were also found to be successful, with R^2 ranging from 0.94–0.98 (McCarty et al., 2002). The use of infrared spectroscopy for the prediction of various carbon fractions, including labile and recalcitrant carbon fractions ($R^2 = 0.89$ – 0.97), had been proven to be successful (Zimmermann et al., 2007). In the MIR range, organic carbon may also be identified by absorption peaks at approximately 2920 and 1230 cm^{-1} (Zimmermann et al., 2007), while carbonates may be identified by strong and numerous absorption bands at 1450, 1060, 880 and 700 cm^{-1} (Clark et al., 1990) (as shown in Fig. 2). In the NIR range, organic carbon can be related to absorption peaks at approximately 600, 1910 and 2100 nm, while carbonates may be identified by peaks at 2300–2350 nm (Clark et al., 1990).

Although soil pH is non spectrally active, it is one of the soil properties that is predicted quite well ($R^2 = 0.57$ – 0.79) because of its relationship with exchange sites related to clay minerals and organic matter (Soriano-Disla et al., 2014).

Infrared spectroscopy has been used successfully to predict exchangeable cation related properties. While cation exchange capacity (CEC) is not a spectrally active component, it has a strong correlation with clay mineralogy and soil organic matter content (Stenberg et al., 2010), particularly absorbance of peaks near 2926–2850 cm^{-1} , and carboxylate species 1633–1413 cm^{-1} . Greater prediction accuracy for certain cations (Ca^{2+} , Mg^{2+} , and K^{+}) with R^2 of 0.70–0.84 compared to Na^{+} ($R^2 = 0.32$) was most likely because those cations are dominant on the exchange sites.

Infrared spectroscopy has also been used to predict nutrients in the soil, particularly the nitrogen (N), phosphorus (P), and potassium (K) concentrations in the soil. However, most studies have shown that only the total amount of nutrients can be well predicted as this relates to soil minerals and organic matter. Available nutrients cannot be well-predicted because they are determined by extraction and solution from soil. Integration of the prediction of plant nutrients and fertilizer recommendations maximizes the nutrient management in the agroecosystems.

Soil biological properties

The correlation of soil biological properties and organic carbon enables the biological properties to be successfully predicted using spectral features. Infrared spectroscopy has been used for the rapid assessment of a range of biological properties, including microbial biomass, soil respiration, microbial groups, and soil enzymatic activities. No spectral contribution is expected from the microbial biomass because it represents roughly less than 5% of the total organic carbon content (Janik et al., 1998). Successful predictions of biological properties were most likely due to the correlation of biological properties with organic matter or other soil properties that have spectral signatures.

Chang et al. (2001) obtained R^2 of 0.6 for biomass C using NIR. Meanwhile, Janik et al. (1998) and Ludwig et al. (2015) reported greater accuracy for the microbial biomass C predictions with MIR ($R^2 = 0.69$ and 0.79 respectively). In addition to biomass C, biomass N ($R^2 = 0.79$) and P ($R^2 = 0.62$) were also determined with moderate accuracy by Ludwig et al. (2015).

A better prediction was reported by Chang et al. (2001) using NIR for microbial respiration than the soil microbial biomass with R^2 of 0.72, 0.66, and 0.82 for mineralizable N, total respiration rate and basal respiration rate (BSR), respectively. van Groenigen et al. (2003) reported greater accuracy for mineralizable N using NIR ($R^2 = 0.46$) compared to MIR ($R^2 = 0.21$) in flooded soils. Similarly, Ludwig et al. (2015) reported an acceptable accuracy of $R^2 = 0.63$ for BSR using MIR.

Microbial biomarkers have also been utilized as a biological indicator of change in the microbial community because the size of microbial biomass itself is not sufficient to explain the effect of certain management regimes. Zornoza et al. (2008) successfully predicted several variables related to soil microbial groups based on PLFA biomarkers: bacteria ($R^2 = 0.93$), G+ bacteria ($R^2 = 0.91$), actinomycetes ($R^2 = 0.92$), VAM fungi ($R^2 = 0.91$) and PLFAs ($R^2 = 0.91$).

The presence of soil enzymes can be linked to soil physico-chemical properties. Although 500 enzymes might be present, only a handful have been identified and measured to date. Reeves et al. (2000) achieved an R^2 within the range of 0.8 with NIR to predict four enzymes (dehydrogenase, phosphatase, arylsulfatase and urease).

Soil contaminants

Contaminants include a wide range of natural and synthetic materials that can be found in soil. Given that exposure to contaminants leads to detrimental effects on human health and ecosystems, there is a need to develop rapid, low-cost methods to assess the spatial and temporal variation of soil contaminants. The application of spectroscopy in detecting contaminants is beneficial for rapid screening to determine whether contamination exceeds a certain threshold and if remediation is required. The prediction of organic contaminants can be directly related to the absorption peaks in the spectra because of sensitivity of the IR method to organic materials. Nonetheless, these absorbances of the organic contaminants overlapped with other organic and inorganic components that exist in the soil throughout the electromagnetic spectrum. Several examples of organic pollutants include petroleum hydrocarbons, microplastics and pesticides.

Absorbance peaks at 2222–2439 nm and 3000–2600 cm^{-1} in the NIR and MIR region have been used to predict the total petroleum hydrocarbon concentration (Forrester et al., 2013) with high accuracy. The peaks in the MIR region are related to two $-\text{CH}_3$ peaks (2950 and 2730 cm^{-1}), which were absent in the natural soil organic matter absorption $-\text{CH}_2$ region at 2930–2850 cm^{-1} . A similar range in the NIR region at 2250–2350 nm was reported by Chakraborty et al. (2010) for the prediction of total petroleum hydrocarbon, which achieved good accuracy in moist intact soil. The absorption at 2200 nm is due to the O—H bonds in the clay minerals, such as kaolinite, illite, and smectite, while absorptions between 2250 and 2450 nm were associated with the C—H bonds in the organic matter and carbonates (Clark et al., 1990).

Absorptions between 1130 and 1720 nm in the NIR range have been reported in various studies (e.g. Sato et al., 2003) in the identification of plastic polymers, such as polyethylene terephthalate (PET) and low density polyethylene (LDPE). Absorbance at 1210, 1420 and 1730 nm is due to C—H (CH_2) first and second overtones and C—H deformation (Sato et al., 2003), while absorbance at 1660 nm is related to overtone stretching of aromatic C—H groups which is present in PET but not LDPE.

Hermansen et al. (2020) successfully utilized NIR for predicting glyphosate (an active ingredient in herbicides) sorption in soil ($R^2 = 0.93$). Bengtsson et al. (2007) also successfully utilized NIR as a tool to predict other pesticide sorption in soil, particularly lindane ($R^2 = 0.85$) and linuron ($R^2 = 0.84$), despite no specific wavelengths being identified.

Although inorganic contaminants, such as heavy metals are not spectrally active, diagnostic screening is made possible due to the relationship with iron oxides, clay, and organic matter. Gholizadeh et al. (2015) using the vis–NIR range detected heavy metal

concentrations (Cu, Pb, Zn and Cd), which had low to moderate to correlations with clay and/or organic matter content, whereas Mn did not have a dependence on clay and organic matter. Similarly, Kemper and Sommer (2002) achieved good R^2 accuracy for the prediction of As (0.84), Fe (0.72), Hg (0.96), Pb (0.95) and Sb (0.93).

Lower cost - miniaturized spectrometer

Lower cost and miniaturized spectrometers with a limited NIR spectral range are now widely available and can potentially enable NIR measurements of soil properties to be used more broadly. For example, a miniaturized Michelson interferometer can be built using monolithic micro-electro-mechanical systems (MEMS). A case study in Australia demonstrates that a miniaturized spectrometer operating at 1250–2500 nm provides comparable accuracy with the complete vis–NIR spectrometer (400–2500 nm) in predicting soil pH, CEC and exchangeable Ca and Mg ($R^2 > 0.63$ –0.78), and slightly less accurate predictions of total carbon, sand, and clay ($R^2 > 0.70$ –0.80) (Tang et al., 2020).

Conclusions

Soil spectroscopy is a viable measurement technology with untapped possibilities. Soil reflectance in the visible-, near- and mid-infrared offers rapid, cheap, and relatively accurate predictions for several soil properties. A single infrared spectrum can offer the prediction of numerous soil properties. The MIR spectra have been shown to provide signatures that can be used to derive many physical, chemical and biological properties. The mechanisms for the prediction of soil properties are due to the direct and indirect interaction between the soil properties and the organic matter and mineral components of soil. Infrared can predict fundamental soil properties related to the soil matrix or solid constituents and soil solution concentrations in equilibrium with the solid phase. Soil properties that do not have active spectral components can be predicted if they are correlated to the mineral or organic components of the soil. However, soil spectroscopy has been mainly used in research studies and has not been widely used as a routine analysis method in agriculture.

Abstract

Electron microscopic methods are powerful tools for soil chemistry investigations. This chapter introduces the fundamental principles and instrumentation of the transmission electron microscope (TEM), scanning electron microscope (SEM), and energy dispersal spectroscopy (EDS). These techniques are important for the morphological characterization and analysis of the chemical composition of soil particles. The applications of these techniques in organic matter–mineral interaction and soil remediation are addressed. Moreover, electron microscope-based new technologies (e.g., scanning transmission electron microscope, cryo-electron microscope, environmental scanning electron microscope) are briefly introduced. Finally, an outlook for the application potentials of aberration corrected-electron microscope in soil chemistry is given.

Key points

- Fundamental principles and instrumentation of TEM and SEM are introduced;
- TEM and SEM are important for soil particle characterization and soil chemical composition analysis;
- Applications of TEM and SEM in SOM–mineral interaction and soil contamination/remediation are overviewed;
- Electron microscope-based new technologies could bring new breakthroughs in soil chemistry.

Nomenclature

AC-EM	Aberration-corrected electron microscope
ACF	Auto-correlation function
BSE	Backscattered electrons
Cryo-EM	Cryogenic electron microscopy
Cs	Spherical aberration
EDS	Energy dispersive X-ray analysis
EELS	Electron energy loss spectrometry
ESEM	Environment scanning electron microscope
FFT	Fast Fourier transform
HA	Humic acid
HNTs	Halloysite nanotubes
HR-TEM	High-resolution TEM
nZVI	Zero-valent iron
PCP	Pentachlorophenol
SAED	Selected area electron diffraction
SE	Secondary electrons
SEM	Scanning electron microscope
SOM	Soil organic matter
STEM	Scanning transmission electron microscope
TEM	Transmission electron microscope

Introduction

The nanoscale surface and structure of soil particles are rarely resolved by light microscopes due to their limited resolution (~200 nm). Electron microscopes were first developed in the 1930s, opening up the world of particles and materials at the nano-scale level. There are two main types of electron microscopes: transmission electron microscope (TEM) and scanning electron microscope (SEM). Energy dispersive X-ray analysis (EDS) is an important accessory to the electron microscope, which can provide additional information (e.g., elemental composition) of the detected particles. Nanoparticles are widely present in soils, including nano-scaled clay minerals, Fe (iron), Al (aluminium) and Mn (manganese hydroxide) oxides, and soil organic matter (SOM). These nanoparticles play important roles in maintaining soil functions. Therefore, it is necessary to have a thorough understanding of these soil nanoparticles by characterizing their physical properties, elemental composition, chemical reactivity, and environmental processes. In addition, soil is a main sink for environmental contaminants, and the interactions between soil particles and contaminants are important for understanding the fate of these contaminants. For example, iron oxides, such as ferrihydrite, goethite, and hematite in soil can adsorb heavy metals (e.g., Pb^{2+}) by surface complexation (Liu et al., 2018); SOM is an important sink for nonpolar organic pollutants (e.g., phenanthrene) (Wen et al., 2007). All the above properties and interactions can be understood better with the assistance of electron microscopes.

Therefore, this chapter aims to introduce electron microscopy (SEM, TEM, and EDS) applications in soil chemistry, including (i) fundamental principles and instrumentation; (ii) application for soil particle characterization; (iii) soil chemical composition analysis; (iv) SOM–mineral interaction; and (v) soil contamination and remediation. Finally, electron microscope-based new technologies that could be potentially used in soil chemistry are briefly introduced.

Fundamental principles and instrumentation**Fundamental principles****Fundamental principles**

Electron microscopes are different from light microscopes because they collect the signals from the interaction between electrons and the soil sample to generate an image. The wavelength (λ) of moving electrons (ignoring relativistic correction) is shown in Eq. (1):

$$\lambda = h / \sqrt{2meV_{acc}} \quad (1)$$

where h and V_{acc} are the Plank constant and the acceleration voltage for the electrons, respectively; m is the mass; and e is the charge of an electron. Based on Eq. (1), electron microscopes have much higher resolution (0.1 nm in theory) than optical microscopes which are limited by the wavelength of visible light. However, the resolution of electron microscopes (e.g., TEM) cannot achieve 1 Å because of a certain extent of aberration on the magnetic lenses. The resolution (δ) of a TEM is roughly calculated as Eq. (2):

$$\delta = 1.2 \sqrt[4]{C_s \lambda^3} \quad (2)$$

Thus, resolution is related to V_{acc} , that is a larger V_{acc} is still preferable for higher resolution. It is noted that higher resolution does not always provide true information for the soil and other samples. For example, for a specific clay mineral particle that consists of relatively light elements (e.g., O (oxygen), Mg (magnesium), Si (silica)), high-energy electrons could penetrate the particles and re-enter the substrate or other particles. The image would be ambiguous under this condition.

Transmission electron microscope

As shown in Fig. 1, transmitted electrons consist of directly transmitted electrons, elastically scattered electrons, and inelastically scattered electrons. The TEM mainly relies on the collection of directly transmitted electrons and inelastically scattered electrons through the sample to create an image. Elastically scattered electrons are used to analyze crystal structure. The direction of elastically scattered electrons changes but their wavelengths do not change. Inelastic scattering has a longer wavelength because an energy loss of the incident primary electron occurs. Currently, TEM is widely used for collecting morphological and structural information about soil particles.

Crystalline structure and chemical information are critical in soil chemistry. High-resolution TEM (HR-TEM) responds perfectly to these demands. The HR-TEM developed in the 1960s has been successfully used to image the atomic structure of samples directly. Different from TEM, the HR-TEM is a phase contrast image rather than amplitude imaging, because more than one electron beam is used (Deepak et al., 2015) (Fig. 2). There are two stages in the HR-TEM imaging process: (i) the formation of an object surface wave after the interaction between electron beams and soil sample; (ii) two Fourier transforms (Fig. 2). In detail, the object surface wave obtains the crystal structural information when the electron beam passes through the sample, and the diffraction wave forms on the back focal plane. The diffraction waves at all levels are recombined to obtain the image wave which retains the original phase, and the lattice fringe pattern is obtained at the phase surface.

In addition to high image resolution, another advantage of TEM is the combination of imaging and diffractometry, which can provide the crystal lattice structure of soil samples. Selected area electron diffraction (SAED) with TEM is a powerful method for characterizing the structure of soil samples, including perfect crystals and defect structures. The main principle of SAED is shown in Fig. 3. Diffracted electrons can be focused into a regular arrangement of diffraction spots on the back focal plane by modifying the electromagnetic lenses; they are recorded as electron diffraction patterns. The advantages of SAED include (i) extremely short wavelength (about 2 pm), (ii) strong atomic scattering, and (iii) the ability to examine tiny particles (about 10 nm^3) (Bendersky and Gayle, 2001).

Fig. 1 Fundamental principles of electron microscopes for soil sample observation. The TEM mainly relies on the collection of transmitted electrons through the sample, while SEM collects the response of reflected electrons and photons to generate an image.

Fig. 2 Two Fourier transforms in the HR-TEM imaging process.

Fig. 3 Fundamental principles of the SAED imaging process.

Scanning electron microscope

The SEM collects reflected electrons and photons to generate an image (Fig. 1). It mainly uses secondary electrons (SE), back-scattered electrons (BSE), and characteristic X-rays for sample characterization. The SE with low energy can provide topographic and chemical information on the surface layer at 50 nm. The energy of BSE is equivalent to the primary incident electron, and thus originates from a depth of micrometers from the soil surface (Kwiecińska et al., 2019), which is beneficial for characterizing porosity, and local crystallographic structure of soil samples and other materials.

Energy dispersal spectroscopy

The EDS further widens the application of electron microscopes in soil characterization. Characteristic X-rays are produced when a beam of accelerated electrons bombard the sample surface. The rays can be collected at characteristic wavelengths and their intensities can be measured by EDS. Therefore, it can be used to identify chemical elements of the soil sample qualitatively and quantitatively (Girão et al., 2017). Electron energy loss spectrometry (EELS) is complementary to EDS. The EELS analyzes the loss of energy of electrons that pass through the thin sample (Fig. 1), thus providing information on atomic composition, bonding and oxidation state, surface properties, and distribution of near-neighbor atoms. It is noted that EELS is a much more sensitive technique for light elements, whereas EDS is more suitable for heavy elements (von Harrach et al., 2010).

Instrumentation

TEM

Fig. 4 shows the core components of TEM, including electron gun, anode, electrostatic lenses (condenser, objective, intermediate and project lenses), and a transmitted electron detection system (fluorescent screen, and charge coupled device camera). The electron gun produces a stream of electrons, and these dispersive electrons are focused on to a small, thin, parallel electron beam by condenser lenses. When it strikes the sample or its specimen, the transmitted electron beam is focused by an objective lens, and an image of the sample is created. The image is passed down the column and enlarged through the intermediate and projector lenses. The enlarged image is then projected onto a fluorescent screen or CCD cameras. After further post processing, the final TEM image can be saved (Kwiecińska et al., 2019).

SEM

Fig. 5 shows the core components of SEM, which consists of an electron gun, anode, condenser lenses, scan coil, objective lens, detectors (BSE, SE and X-ray), and amplifier. An electron gun produces a stable electron beam, which will diverge after passing through the anode plate. The first SEM system generally used tungsten "hairpin" or lanthanum hexaboride cathodes, whereas field emission sources are applied widely in the modern SEM; field emission sources can provide enhanced current and lower energy dispersion. A condenser lens is used to converge and collimate the electron beam into a relatively parallel stream. Scanning coils deflect the electron beam so that it can scan the sample surface. The SE and BSE detectors are used to detect different signals. The most frequent type of SE detector is the Everhart Thornley detector, which comprises a biased grid to attract the electrons, a scintillator to convert the SE signal, and a photomultiplier tube to amplify the signal. Semiconductor or scintillator plates usually determine BSE detector types. To enhance chemical or topographic contrast, two to four BSE detectors can be arranged at different solid angles. The X-ray detector counts the number of X-rays at a selected location on the sample. The collected signals are appropriately amplified and digitized. To generate a real-time image viewed on a display screen, the strict correspondence between scanned point and image point of the sample is needed. Finally, the acquired information is stored in a computer.

Fig. 4 Schematic diagram of the core components of TEM.

Fig. 5 Schematic diagram of the core components of SEM.

Strengths and limitations of TEM and SEM

Both TEM and SEM are powerful tools for characterizing soil samples due to their versatility and high spatial resolution compared with light microscope resolution of $\sim 0.2 \mu\text{m}$. As described above, electrons are used to acquire images of samples for both TEM and SEM. The SEM uses a specific set of coils to scan the beam in a raster-like pattern and collect the scattered electrons while TEM uses the transmitted electrons. Some core components of TEM and SEM are the same, including electron guns, electromagnetic lenses and electron apertures. In addition, both TEM and SEM can characterize the morphology of soil samples at the nanoscale. Despite the similarities, TEM and SEM have their unique strengths and limitations.

The TEM offers higher resolution (~ 0.2 nm) than SEM, and can even reach near-atomic resolution for HR-TEM. Additionally, TEM provides information on both element and compound structure (i.e., crystal structure, elemental information and morphology). However, despite the advantages of magnification and versatility, TEM has some limitations. First, TEM samples must be thin enough for electrons to pass through, generally below 150 nm, and in cases that require high-resolution imaging even below 30 nm. Therefore, sectioning is required for the thick soil and biological samples. Then, the samples must be analyzed in a vacuum because the electrons are easily scattered by other molecules in the air. This means that TEM cannot characterize wet samples or biological samples (e.g., proteins, dissolved organic matter); but this limitation can be overcome by the cryo-electron microscope. Furthermore, TEM is sensitive to vibration and electromagnetic fields and must be housed in an area that isolates them from possible exposure.

The SEM provides a 3-D image of the sample by imaging the original morphology of solid surfaces, whereas TEM images are 2-D projections of the sample from the inner structure. The resolution of SEM is about 1 nm which is less than for TEM, and SEM does not need the sample to be sectioned and it can also characterize samples as large as 100 mm. Similar to TEM, SEM cannot characterize wet or biological samples either, which can be overcome by the environmental SEM.

Clearly, there is no “better” technique; it depends on the type of sample that has been prepared and the information required. By combining the advantages of SEM and TEM, the morphological and structural information of soil samples can be understood better. Some limitations of SEM and TEM have been overcome at present by developing electron microscopy-based new technologies (see below). With these improvements, electron microscopes will continue to increase our understanding in soil chemistry.

Applications of electron microscopes in soil chemistry

Morphology of soil particles

The morphology of soil particle provides important information on understanding the shear strength, water-retention ability, and compressibility of soil. Electron microscopes can provide a variety of morphological information (e.g., shape, pore, roughness, and size) for soil particles including minerals present and SOM.

Minerals

Soil minerals occupy almost half of a soil sample. Iron and aluminum oxides are ubiquitously present in soil. These minerals play important roles in the fate, transport, and cycling of nutrients or contaminants in soil. Therefore, it is necessary to characterize these minerals in soil comprehensively. The SEM and TEM are very effective tools for morphological characterization. Information on the morphology of minerals using SEM and TEM can be found in numerous studies. Fig. 6 shows the SEM image for Fe- and Al-rich chlorites from the Strzegom pegmatite (Poland). The SEM provides clear topographic information on the chlorite surface. Most of the chlorites are triangular, prism-like shapes and commonly have a lateral size less than 50 μm . The thickness of each particle is about several microns, which can also be observed from this SEM image. The SEM is also effective in resolving the topographic information for large-size minerals, whereas TEM would be more suitable for the nanoscale minerals. Fig. 7 shows that halloysite nanotubes (HNTs) consist of a transparent central area that is tubular (Cheng et al., 2018). The internal diameter and length of HNTs range from 20 to 30 nm and 0.2–1.7 μm , respectively, and their shell thickness is about 15–20 nm, which could be clearly obtained from TEM imaging.

Soil organic matter

The SOM occupies around 30% (by mass) of typical surface soils; it has a great influence on soil properties (e.g., water retention, the ability to chelate and complex ions, pH) and environmental processes of various elements in soil. Commonly, SOM molecules (e.g., humic acid (HA)) are in the form of long-chain aliphatic structure in water. Fig. 8A shows the aggregation of HA molecules, and a closely-woven flake network structure and a thickened sheet structure with linear-like protrusions can also be observed (Qi et al., 2004), probably from the drying pre-treatment before SEM imaging. The TEM observation in the work of Monreal et al. (2010) showed that SOM molecules and aggregates were attached to the surface of minerals (Fig. 8B), which may be caused by electrostatic attraction and complexation due to abundant oxygen-containing groups in SOM.

Elemental composition and crystalline phases of soil particles

The EDS is a highly specialized technique that can be combined with both TEM and SEM; it is widely used in the analysis of elemental composition of soil particles including both minerals and SOM. In addition, HR-TEM and SAED are powerful for characterizing structural properties of soil particles, including perfect crystals and defects.

SEM-EDS

The SEM images of quartz, sphalerite and magnetite are shown in Fig. 9. The lateral sizes of these particles were about 40, 25, and 200 μm , respectively. After EDS mapping, the main elements on the surface of these minerals were then detected (Drif et al., 2018). Clearly, Si and O were present on the surface of quartz, while Zn and S were on sphalerite (Fig. 9A). For magnetite, Fig. 9B shows that O and Fe were distributed homogeneously.

TEM-EDS and SAED

Kaolinite is a typical mineral in soil. From TEM imaging, the observed kaolinite particles are at the nanoscale, in the form of a laminar structure of pseudo-hexagonal platelets (Suzuki et al., 2013) (Fig. 10A). The EDS-mapping analysis shows that the ratio of the atomic concentration of Al/Si is close to 1.0, which is consistent with the theoretical chemical composition of kaolinite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$) (Fig. 10B). Some minerals (e.g., maghemite and magnetite) have the same elemental composition but different crystal structures, which could be further identified by SAED. For kaolinite, the well crystallized structure was demonstrated based on the its electron diffraction pattern using SAED (Fig. 10C). Therefore, it is concluded that an unknown mineral could be identified by combining SEAD with EDS.

HR-TEM

In addition to SAED, HR-TEM is widely used for crystalline phase analysis. To distinguish the specific minerals of soil nanomagnets, Ahmed and Maher (2018) applied HR-TEM to identify magnetic nanoparticles in fossil soil (paleosol) (Fig. 11). Fig. 11A shows the visible lattice fringe of magnetic nanoparticle using HR-TEM. A structural fingerprinting approach was used to characterize magnetic nanoparticles in the soil further. The structural fingerprinting approach utilizes crystallographic processing of HR-TEM images in which crystal structure factors were obtained using Fourier analysis. The auto-correlation function (ACF) can be used to detect the periodicity of a single ferrite crystal and to reveal composite crystals. As described in the HR-TEM imaging principle (Fig. 2), the

imaging process of a TEM contained twice the FT, Fourier transform (F and F^{-1}). Fast Fourier transform (FFT) was performed by a discrete finite sum in a computer, which greatly decreased the computation time. After FFT and ACF analysis of the HR-TEM image (Fig. 11A), FFT power spectra and lattice plane distances of the magnetic nanoparticles could be acquired (Fig. 11B and C), and the magnetite crystals were successfully identified in this soil sample.

Soil organic matter-mineral interaction

The SOM commonly serves as a redox mediator in mineral transformation in the natural environment. For example, abundant oxygen-containing functional groups (e.g., -OH, -COOH) on HA can promote its interaction with minerals, such as adsorption and transformation. TEM-EDS could be the first choice for the investigation of HA-mineral interaction at the nano-scale level. Here we given an example of the role of HA in siderite transformation (Xing et al., 2020). Fig. 12 shows the TEM image of siderite after incubation with HA, in which spherical particles (area A), clusters (area B), and rod-like structures (area C) were observed. Combined with EDS-mapping, these nanoparticles were identified as siderite, ferrihydrite, and goethite (FeOOH), respectively. The elements Fe and C were the major elements for siderite (area A) and ferrihydrite (area B), whereas element C was rare in goethite (area C). This result implied that the newly formed goethite did not adsorb HA. The expulsion of HA indicated that the bonds between HA and Fe atoms were broken during the transformation of siderite to goethite. Moreover, phosphate can be adsorbed on both siderite and the newly-formed goethite, which is clearly shown in Fig. 12.

Fig. 12 The TEM-EDS mapping of siderite after incubating with HA and phosphate. Before observation, the samples were lyophilized for 12 h after aging for 7 days. Reproduced with permission from Xing B, Graham N and Yu W (2020) Transformation of siderite to goethite by humic acid in the natural environment. *Communications Chemistry* 3(1): 1–11.

Soil contamination and remediation

Soil contamination by heavy metals raises increasing concerns worldwide. Quick and reliable detection of the species and abundance of heavy metals are crucial for soil monitoring and remediation. The EDS is a valid method to analyze the distribution of heavy metals on both minerals and SOM. Lime was applied by Hamid et al. (2020) to remediate Cd and Pb that co-contaminated soil. From SEM imaging, lime showed irregular structure after amendment (Fig. 13). The EDS mapping demonstrated the distribution of Cd and Pb on the lime, indicating that Cd and Pb were removed by lime.

Moreover, TEM-EDS analysis was performed to investigate the underlying mechanisms of soil remediation by zero-valent iron (nZVI) coupled with the increase in rice production (Liu et al., 2020). The nZVI could be taken up by rice roots, and TEM is more suitable for observing the distribution of nZVI in root tissues than SEM. Fig. 14B shows that numerous nanoparticles are present in rice root intercellular spaces after amendment with nZVI for 30 days in pentachlorophenol (PCP) contaminated soil, whereas no particles can be detected in rice roots without the amendment of nZVI (Fig. 14A). The EDS result demonstrates that these nanoparticles are rich in Fe (Fig. 14B), which indicates the uptake of nZVI or other Fe-based species in roots. It is noted that the specific types of Fe-based minerals cannot be confirmed by only TEM-EDS because nZVI may undergo biotransformation during uptake and transport in plants. The HR-TEM is suitable to confirm further the specific mineral types (e.g., nZVI or other produced Fe-based minerals) in soil. For the case in Fig. 13, if the heavy metals (e.g., Cd, Pb) were mineralized during remediation, the minerals formed could also be identified by HR-TEM.

Electron microscope-based new technologies in soil chemistry

Over the last few years, electron microscope-based new technologies have been developed, mainly in material and biological fields. Although they have not been widely applied in soil chemistry, potential uses have been observed based on currently limited applications. Hence, we provide typical examples on the applications of some important electron microscope-based new technologies in soil chemistry.

Scanning transmission electron microscope (STEM) and cryogenic electron microscopy (cryo-EM)

The STEM, which combines the advantages of TEM and SEM, is a very powerful instrument for the characterization of soil samples. Similar to TEM, STEM requires very thin samples or their ultrathin sections. The principal advantage over TEM is that STEM is equipped with scanning coils that can collect simultaneously signals from both reflected and transmitted electrons. Fig. 15A and B shows the topological structure and nanometer scale spatial resolution images provided by STEM of the organic–organic interface of

the sampled minerals (Possinger et al., 2020). Compared with the surrounding matrix, the organo–organic interface can be clearly identified (the region marked with the white square in Fig. 15A).

Cryo-EM is an advanced electron microscopy technique for the observation of wet or biological samples, and these samples should be cooled by liquid nitrogen to cryogenic temperatures and embedded in an environment of vitreous water. Currently, cryo-EM is used mainly in structural biology and materials science, especially for the high-resolution structural determination of biomolecules in solution. In soil chemistry, this technique can keep the soil sample in its original state by avoiding possible morphological and structural changes during drying pre-treatment. Therefore, cryo-EM could be further used to investigate the organo–organic interface by preventing possible conformation changes or the formation of large crystals of ice in the soil sample

(Possinger et al., 2020). In Fig. 15B, only small ice crystals could be found, which is because the samples were rapidly cooled by immersion in liquid nitrogen (average temperature -207°C) to decrease the size of ice crystals relative to a standard freezer (e.g., -20 to -80°C). Furthermore, STEM combined with EELS can provide organic elemental information. The EELS elemental map shows the patchy distribution of nitrogen and carbon in the organic–organic interface region, and two distinct carbon bonding environments (Fig. 15C). After further analysis by carbon K-edge multivariate curve resolution, the two types of carbon bonds were assigned to $\text{C}=\text{C}$ bonds associated with aromatic structures, and alkyl $\text{C}-\text{H}$ bonds with a variety of transitions, respectively (Fig. 15D and E). This work combines STEM, cryo-EM and EELS, successfully providing comprehensive information on the organic–organic interface and enabling direct visualization and interface analysis.

Environmental scanning electron microscope (ESEM)

The ESEM has been defined as a SEM capable of maintaining a minimum water vapor pressure of at least 609 Pa in its specimen chamber. It has a simple procedure for sample preparation, a good depth of field, and a higher permitted gas pressure. Therefore, ESEM is extremely important for the direct characterization of biological samples by controlling the relative humidity, which is a considerable advantage compared with SEM. Li et al. (2020) used ESEM to investigate the internalization pathway of microplastics ($\sim 2\text{ }\mu\text{m}$) in a wheat seedling. By avoiding drying, the large gap between the epidermal cells at the site of the lateral root was observed in the wheat seedling (Fig. 16). The observed gaps were further confirmed as the main pathway for microplastics uptake. This result indicates that ESEM has great application potential in investigating the original sample morphology of plants as well as other organisms in soil. In addition, ESEM is also suitable for investigating the pore structures of minerals which are sensitive to water (e.g., bentonite).

SEM–Raman system

Although SEM is effective for characterizing the surface morphology of mineral samples, the structural and electronic information with diffraction were unknown. The Raman spectrometer can offer fundamental spectral information on the molecular structure of a given mineral, while the morphology can be obtained only by the light microscope which has a much lower resolution than SEM. A combination of these two techniques in a single system (SEM–Raman) could fulfill the above requirements during mineral characterization. For example, the SEM–Raman system was applied to track in-situ the morphological and spectral information of a newly-formed Pb-based mineral (Wu et al., 2020). The SEM image in Fig. 17 shows that Pb-based minerals are mainly scale-like, which cannot be observed clearly by the light microscope. Specific regions were further analyzed in-situ by the Raman spectrometer. The Raman spectra obtained display peaks at 1440 , 1480 , and 1590 cm^{-1} , confirming that the secondary mineral was Pb oxalate. Of note, the small and large Pb oxalate particles show distinct intensities of specific peaks in Raman mode, indicating the variable orientation of the secondary Pb mineral. To the best of our knowledge, this is the only current research that has focused on soil/mineral characterization by SEM–Raman. With its excellent performance, SEM–Raman may become widely applied in soil science in the future.

Aberration-corrected electron microscope (AC-EM)

To correct the aberration, a corrector is installed in the objective lens and/or the condenser of an electron microscope, and this kind of electron microscope is called an AC-EM. Resolution of the AC-EM is as low as 0.05 nm due to the elimination of spherical aberration (Cs). The Cs corrector of TEM is installed in objective lenses, whereas it is installed in condenser lenses for AC-STEM. Sometimes, Cs correctors can be installed in both condenser and objective lens, which is called the double spherical aberration electron microscope. With its extremely high resolution, AC-EM has been widely applied in the characterization of some crystalline solids (e.g., Au (gold), GaN (gallium nitride), and other crystals) to resolve individual atomic structures in the field of material science. In addition to atomic structure, the chemical bonds (e.g., C—C bond) could be observed in graphene sheets. However, the application of AC-EM in soil chemistry has not been reported to our knowledge.

Summary

The SEM and TEM with high spatial resolution in both morphological and structural characterization have been confirmed to be extremely useful, highly versatile techniques for soil particle analysis over the past few years. In this chapter, we have summarized the foundational principles and key instrumentation of SEM, TEM and EDS. The SEM uses mainly SE, BSE while TEM collects transmitted electrons to create images. As a result, TEM offers valuable information on the inner structure of a sample while SEM provides information on the surface. The EDS mainly utilizes characteristic X-rays to display qualitative and quantitative information, and the spatial distribution of chemical elements in soil samples. In addition, applications of TEM and SEM in the characterization of soil minerals and SOM are introduced and show that SEM provides 3-D information, whereas TEM images are 2-D projections of the soil from the inner structure. The TEM is more effective for collecting structural and atomic information (crystalline/amorphous, lattice finger pattern, crystal face) of soil particles than SEM. By combining with SEM or TEM, EDS can obtain elemental species and their distribution in the soil sample. In addition to soil particle characterization, TEM, SEM and EDS play an important role in the investigation of SOM–mineral interactions and soil contamination/remediation; some examples are provided in this chapter. Moreover, we introduced some electron microscope-based new techniques including STEM, cryo-EM, ESEM, SEM–Raman and AC-EM, together with their applications in soil chemistry. The STEM takes advantage of both SEM and TEM techniques in soil particle analysis. Cryo-EM and ESEM overcome vacuum limitations, and are suitable for the observation of biological samples (e.g., plant tissues). The SEM–Raman system can give both morphological and structural information of minerals during in-situ observations. The resolution of AC-EM can achieve up to 0.05 nm, and information on the atomic or chemical bonds can be collected. Electron microscopes will continue to improve our understanding of micro-nanoscale physical and chemical characteristics of soil particles.

Abstract

Atomic force microscopy (AFM) provides a unique opportunity to identify the nanoscale processes on environmental interfaces. The NOM-mediated transformation of engineered nanomaterials and the role of substrate symmetry and epitaxial growth of ordered aggregates can be detected from AFM imaging. Kelvin probe force microscopy (KPFM) helps identification of the asymmetric surface charge of clay particles as well as screw dislocation-assisted growth of colloidal heteroaggregates prevalent on interfaces. Colloidal probe force microscopic (CPFM) evaluation of nanoscale forces determines the relative efficiencies of organic and inorganic cations, structural heterogeneity of NOM (natural organic matter), and hematite nanominerals in stable soil aggregate formations between silica and clay.

Glossary

- μ** An elastic modulus is a quantity that measures an object or substance's resistance to being deformed elastically when stress is applied.
- B** Burgers vector named after the Dutch physicist Jan Burgers is a vector, that represents the magnitude and direction of the lattice distortion resulting from a dislocation in a crystal lattice.
- H** Hamaker Constant is defined for a van der Waals body-body interaction.
- k** Spring constant defines the stiffness of the Hookean spring.
- r** Separation distance between the centers of the interacting particles.
- γ** Surface energy is defined as the work per unit area produced by the force that creates the new surface.
- ϵ** The dielectric constant of a solvent is a measure of its polarity.
- ϵ_0** Permittivity of the free space. A physical constant is used in electromagnetism and represents the capability of a vacuum to permit electric fields.
- κ^{-1}** Debye length represents the thickness of the electrical double layer.
- σ** Distance at which the intermolecular potential between the two particles is zero.
- σ_1 and σ_2** The surface charge densities of the two surfaces. The amount of charge per unit area.
- ϕ** Phase angle refers to the angular component of a periodic wave.
- ϕ** The work function is defined as the minimum amount of energy required to remove an electron from a solid to a point in the vacuum immediately outside the solid surface.
- ζ** Raleigh damping.

Key points

- A brief introduction of AFM-based experimental techniques to elucidate the mechanism of nanoscale environmental phenomena.
- The role of NOM-mediated environmental transformation of anthropogenic nanomaterials on an air–water interface and subsequent heteroaggregation with a natural clay colloid. A screw dislocation-driven growth of a colloid cluster.
- Role of hematite nanominerals, NOM, and cationic species on the adhesion of silica and clay platelets. Role of nanoscale forces on primary soil aggregate formation.

Introduction

Discovery of the generic scanning probe microscope in the early 1980s has opened up the potential application of both scanning tunneling microscopy (STM) and atomic force microscopy (AFM)-based techniques. This discovery by G. Binnig and H. Rohrer of the IBM Zurich Research laboratories, Switzerland brought them the Noble Prize for Physics in 1986. The development of AFM applications in soil science and geochemistry enriches our understanding of several fundamental nanoscale processes occurring on environmental interfaces starting from mineral dissolution to bacterial adhesion. Nanometer-scale resolution of AFM (up to 0.5 nm), non-invasive sample measurement techniques with minimal sample damage, and its operational flexibility in a wide range of environmental conditions have furthered the scope of identifying nanoscale processes and the characterization of soil colloids on environmental interfaces. The working principle of AFM relies on the fact that a sharp tip attached to the end of a microcantilever with a spring constant (k_c) raster scans a portion of the sample surface resulting in an attractive force between the tip and the surface. The cantilever deflection (q) produced from the tip-substrate interaction corresponds to a harmonic oscillator with upward restoring force following Hooke's law as shown schematically (Fig. 1) (Reifenberger, 2016). At equilibrium, this restoring force must be equal and opposite to the interaction force that caused the deflection. During the movement of the tip across the substrate, the surface contour controls the tip movement and subsequently alters the cantilever deflections and maps the substrate surface.

Early generation AFM assembly involves the determination of interaction forces between the probe and sample holder, which undergoes upward and downward movement to control probe–sample distance. However, in the new generation AFM machines, the cantilever is attached to the piezoelectric sensor fixed to the piezoelectric tube to maintain constant interaction force. The probe scans the surface and a topographic image is obtained after acquiring the vertical control signals with upward and downward movement of the cantilever according to the surface morphology, while the interaction forces remain constant during scanning by supplying the current through a feedback loop. Piezoelectric ceramics are materials that expand or contract in the presence of a voltage gradient and facilitate the creation of a three-dimensional positioning device with high precision. The precision of vertical and lateral deflections of the cantilever is controlled by the optical lever with the reflection of a laser beam from the back of the cantilever to a photodiode. The differences between the segments of the photo-detector signals indicate the position of the laser spot on the detector and thus the angular deflections of the cantilever. The image data are sampled digitally at equally spaced intervals, generally from 64 to 2048 points per line.

Fig. 1 Hooke's law of harmonic oscillator and schematic diagram of the AFM set up.

Modes of AFM operation

Contact mode AFM

The AFM not only measures the force on the sample but also regulates it, allowing the acquisition of images at very low forces. In contact mode, AFM uses the feedback loop voltage to regulate the force on the sample. The assembly of the feedback loop consists of a tube scanner that controls the height of the tip, the cantilever, and the optical lever, which measures the local height of the sample; and a feedback circuit that attempts to keep the cantilever deflection constant by adjusting the voltage applied to the scanner. A well-constructed feedback loop is essential to performance of the microscope. During scanning, a constant bend in the cantilever is maintained. This bend corresponds to a displacement of the tip representing the height of the sample. The major limitations of the contact mode AFM operations include contamination and deformation of the samples because a significant amount of force has been required to move the probe across the substrate (<https://www.azonano.com/article>).

Application to mineral dissolution

The application of contact mode AFM imaging equipped with a fluid cell has facilitated our understanding of the mineral–water interface governing several key environmental issues, ranging from nutrient cycling to biomineralization processes. Monitoring of in situ mineral dissolution, nucleation and growth of the crystal, and epitaxial precipitation reactions of metal ions has improved our understanding of the role of biogeochemical cycling. The capability of AFM fluid cells relies on recording the dynamic evolution of mineral topographies, formation, and migration of steps. A comprehensive review of the application of contact mode AFM is given by Maurice (1996) and Hochella et al. (1999).

Non-contact (NC)- and tapping mode (TM)-AFM imaging

The limitations of contact mode AFM imaging resulted in the evolution of non-contact mode AFM imaging by Martin et al. (1987). In this mode, an oscillating probe hovers $\sim 50\text{--}150\text{ \AA}$ above the sample surface to sense the attractive van der Waal's force resulting in a shift in the resonance frequency of the cantilever. The alteration in both the amplitude and phase of the cantilever has been monitored by the feedback loop to control tip–sample distance.

The non-contact mode provides very good resolution of the height of the sample but with reduced lateral resolution. The application of non-contact mode AFM in ambient conditions requires maintenance of a constant tip–sample distance and prevention of the tip contacting the sample surface. The major limitation of non-contact mode imaging is that once the tip makes accidental contact with the sample the tip can get stuck and perturb the imaging process. The operation of non-contact AFM in the fluid is extremely difficult since the fluid layer is substantially thicker than the range of the van der Waals force gradient. Therefore, imaging of the true surface with non-contact AFM fails because the oscillating probe becomes trapped in the fluid layer.

The advent of tapping mode AFM (TMAFM) has substantially improved the limitations of the non-contact mode. To prevent the AFM tip from sticking to the substrate surface in non-contact mode a deliberate 'tapping' is introduced in which the tip strikes against the substrate surface and detaches on each oscillation cycle by using a large vibrational amplitude. In regular TMAFM, the probe oscillates at its fundamental resonance frequency with constant adjustment of the tip's vertical position to maintain a constant oscillation amplitude while scanning a surface. The higher amplitude of oscillation that makes intermittent contact with the substrate in each cycle provides improved vertical and lateral resolution and the capability of imaging in a liquid environment (<https://www.azonano.com/article>). In TMAFM, dynamic vibration of the cantilever can be divided into three zones including free, transition, and contact vibration zones (Chan and Green, 2006). Therefore, TMAFM can be applied for imaging soft biological samples as well as having operational capability in a liquid medium including imaging of soil colloid particles in their natural hydrated state. The TMAFM phase of imaging has significant application in identifying the properties of materials. The phase shift is interpreted as being the phase lag between the driving voltage signal and the actual displacement response of the cantilever. In TMAFM generally, silicon (Si) tips with cantilever lengths of 125 and 225 μm and resonant frequencies of 298 to 355 kHz and 67 to 94 kHz are used (Namjesnik-Dejanovic and Maurice, 2000). However, in a liquid environment, a silicon nitride (Si_3N_4) tip with a shorter cantilever length (100 μm), resonance frequency 0–50 kHz, and 0.032 Nm^{-1} spring constant were used. Except for free vibration amplitude and resonance frequency of the cantilever, the quality (Q) factor depends significantly on the experimental environment and on the damping ratio (ζ): $Q = \frac{1}{2\zeta}$, ζ is one of the parameters determining the Raleigh damping as shown schematically in Fig. 2 (Deng et al., 2015). Damping of the cantilever while imaging in solution necessitated enhancement of the drive amplitude with stronger vibration of the probes; however, this may damage soft materials adsorbed on the substrate surfaces. The damping-induced limitation of the cantilever in TMAFM has been improved by the introduction of Peak force tapping technology. In this process, a constant feedback loop is maintained by applying a sinusoidal ramping instead of linear ramping used in regular tapping mode at forces of 100 pN or less. In this process, as the tip approaches the surface the velocity tends to be zero enabling more accurate and direct control of the tip–sample interaction force. Recently high-speed frequency modulation AFM (FM-AFM) has enabled true atomic-resolution of calcite in liquid at $\sim 1\text{ frame s}^{-1}$, which is ~ 50 times faster than the conventional FM-AFM (Miyata et al., 2017). The surface features of the moving step edges of calcite were detected during dissolution in water at the subnanometer scale.

Fig. 2 (A) The range of AFM application regime. (B) resonance frequency of the cantilever in air and frequency shift due to tip–substrate attractive and repulsive forces and (C) damping of the cantilever oscillation in a fluid medium (<https://www.azonano.com/article>).

Application of TMAFM imaging in air and aqueous medium

The molecular conformation of the natural organic matter (NOM) molecules has a profound role in the entrapment of contaminants including hydrophobic organic compounds (HOCs). A correlation between NOM conformation and sorption behavior of heavy metal ions was determined by Liu et al. (2001) with ex-situ AFM imaging. Namjesnik-Dejanovic and Maurice (2000) applied in situ AFM to identify the role of solution properties including pH, ionic strength, concentration, and nature of the exchangeable cations on NOM conformation on mica and hematite substrates. At relatively low NOM concentrations (20–50 mg C L⁻¹), and intermediate pH (5–6), NOM molecules isolated from groundwater produced small micellar aggregates on mica due to cation-assisted charge screening. However, at 100 mg C L⁻¹ NOM concentration ring and toroidal structures were detected. The phase-contrast imaging of NOM on a hematite substrate revealed the development of flattened disk, ring-shaped and spherical structures and accords with the conformation of the Fe-NOM complex solutions viewed from X-ray microscopy (Myneni et al., 1999). Pan et al. (2008) have shown a correlation between HOC sorption and NOM conformation as a function of solution variables including pH, ionic strength, and concentration. The phase-contrast TMAFM imaging provides the opportunity to identify the interaction of NOM with mineral colloids including anthropogenic NPs as well as adhesion of NOM molecules to mineral particles isolated from the groundwater (Plasche et al., 2002).

Our previous investigations have elucidated the mechanistic difference in suspension instability of aluminum oxide NPs in the presence of low molecular weight Aldrich humic acid (HA) and the high molecular weight soil-derived HA7 fraction from Amherst peat (Fig. 3A–C). The TMAFM imaging and the dynamic light scattering (DLS) measurements revealed that Aldrich HA induced charge neutralization of an Al₂O₃ NPs suspension, and specifically at a higher concentration of the former it facilitated stronger van der Waals attraction resulting in destabilization of the colloidal suspension. Nonetheless, even at a lower concentration of high molecular weight HA7, Al₂O₃ NPs undergo significant flocculation. The TMAFM imaging of the HA7-Al₂O₃ NPs mixture revealed that the long-chain fractions of HA7 with a large radius of gyration (the root-mean-square distance between each atom in the molecule and the center of mass of the molecule itself, normalized for the number of atoms) anchors on several Al₂O₃ NPs facilitated bridging flocculation, specifically at low ionic strength (Ghosh et al., 2008) (Fig. 3). The TMAFM image of single Al₂O₃ NP showed a positive phase shift due to repulsive interaction between NPs and the hard probe while a negative phase shift was detected from the viscoelastic drag in HA7-modified Al₂O₃ NPs.

Unlike at the low concentration of HA7, the complete surface modification of Al₂O₃ NPs by HA7 at higher ionic strength resulted in the formation of an HA7 corona with the enhancement of colloidal stability (Fig. 3D–F). The TMAFM image of bare Al₂O₃ NPs at pH 5 on Ca²⁺-adsorbed mica showed significant aggregation as seen from the AFM height and large repulsive phase shift (Fig. 3D and inset). Therefore, it follows the classical Derjaguin–Landau–Veerwey–Overbeek (DLVO) model of colloidal aggregation. In contrast, HA7-coated Al₂O₃ NPs were predominantly separated from each other with reduced aggregation evident from the height image and it complies with the dynamic light scattering (DLS) data (Ghosh et al., 2010). The AFM phase image of the HA7-coated NPs at pH 5 exhibited a dark corona of adsorbed HA7 molecules around the core NP due to the viscoelastic drag between the soft HA 7 molecules and the hard tip (Fig. 3E and F). The enhanced suspension stability of HA7-coated Al₂O₃ NPs arises from the overlapping of excluded volumes of the coated NPs resulting in steric stabilization. Flory–Krigbaum’s statistical thermodynamic theory of polymer solvation clearly explained that as the coils of the adsorbed macromolecules overlap, the concentration of the polymer doubles in that overlapping region, and the system becomes thermodynamically unstable ($\Delta G > 0$). This causes the instantaneous movement of the water molecules within the lens-like overlapping zone with an overall rise in colloidal stability due to entropic depletion repulsion.

Role of substrate symmetry and electric dipole on the epitaxial growth

The air–water interface prevalent in unsaturated soils is the hotspot of environmental interactions of anthropogenic nanomaterials (NM) with mineral particles and NOM molecules. The nanoscale resolution of AFM and the capability of imaging with a fluid cell bolsters the possibility of identifying the interfacial processes regarding dissolution, transformation, and heteroassociation of anthropogenic colloids in diverse porewater compositions. Numerous applications of Ag (silver) NPs including antibacterial and

Fig. 3 (A) The TMAFM phase image produced from repulsive interactions between the hard silicon cantilever and aluminum oxide NPs with a positive phase shift, (B and C) TMAFM height and phase contrast images of aluminum oxide NPs and HA7 mixture. The presence of long-chain biomolecules in high molecular weight HA7 contributed to bridging flocculation, (D) TMAFM height and phase images (inset) of aluminum oxide NPs in Ca²⁺-saturated mica substrate, reflecting significant aggregation according to the DLVO model. The inset shows a large positive phase shift due to probe-cluster repulsion. However, HA7-coated aluminum oxide showed enhanced colloidal stability, (E) height, and (F) phase images of HA7-coated aluminum oxide revealing steric stabilization (Ghosh et al., 2008, 2010).

catalytic properties and greater production facilitated its environmental incorporation into soil. The Ag⁺ produced from the particle dissolution and formation of reactive oxygen species (ROS) caused toxicity to organisms. The AFM height imaging coupled with nanolithography techniques provides a convenient way of measuring the dissolution kinetics of AgNP in an air-saturated salt solution (Liu et al., 2018). Except for the dissolution of metallic NPs, our study has shown the interfacial transformation of carbonaceous fullerene water suspension (FWS) i.e. nC₆₀ in the presence of tannic acid (TA), a surrogate of NOM (Ghosh et al., 2019).

The TMAFM image of FWS showed the formation of spherical 3-D clusters (height above 10–15 nm) due to their inherent hydrophobicity specifically on the hydrophilic mica surface (Fig. 4A–D). However, π electron transfer from TA molecules to electron-deficient fullerene and consequent surface hydroxylation produce oligomeric 1-D arrangements evident from AFM height images on the mica surface. The interfacial heteroassociation of FWS with Na-saturated kaolinite (Na-KI) produced random aggregates. However, in the presence of TA and Ca²⁺ (added through the inlet port of the AFM fluid cell), heteroassociation of FWS with Na-KI produced 1-D needle structures on the air–water interface. Reduced sorption of TA on negatively charged Na-KI and oligomerization of TA-functionalized fullerene produced an amphiphilic helical backbone and subsequent entrapment of Na-KI particles at the nodes.

We also observed in a muscovite mica substrate symmetry-directed organization of the needles into a 2-D rectangular herringbone motif. The presence of a mirror plane on the dioctahedral muscovite (001) (2-D space group) with almost equal energy particulate attachment sites resulted in V-shaped and 180°-rotated twinned growth of the herringbone motif (Fig. 4E–H, Ghosh et al., 2014, 2019). The minute elevation due to the difference in orientation of the –OH groups below the quasi-hexagonal silica tetrahedral layer on mica in the α (001) and β (001) cleavage planes has resulted in an almost 60° orientation between the arms of the V-shaped structures (indicated by the black lines), equivalent to a 120° mutual rotation. However, the more complex geometry of the colloid cluster would probably occur on a trioctahedral phlogopite mica (2-D space group $p31m$) with three mirror axes and higher rotational degrees of freedom. The lower dimension of the FWS due to TA-assisted functionalization and the electric

Fig. 4 The AFM height image of (A) FWS and (B) TA-assisted oligomerization of FWS and amphiphilic arrangement of the functionalized fullerene at pH 7, (C) hetero-association of FWS and Na-KI produced random aggregates in the absence of TA and any cationic species at pH 7, (D) Na-KI and FWS mixture in the presence of TA and (E and F) in 10 mM Ca^{2+} on muscovite mica producing the herringbone pattern of aggregates and screw dislocation-driven growth of tubular aggregates, (G) mica substrate preadsorbed with 10 mM K^+ produced helical wire-like aggregates, and (H) at higher particle concentration and on mica substrate treated with K^+ , the ternary mixture produced liquid crystalline aggregates (Ghosh et al., 2019).

field produced by the exchangeable K^+ on mica facilitated the growth of the needle. The role of exchangeable K^+ was evident from the liquid crystalline arrangement of particles on the air–water interface. Low-energy electron diffraction (LEED) investigation on freshly cleaved mica has shown that a half monolayer of K^+ facilitates the surface-dipole-directed linear growth. However, Ca^{2+} -mediated enhanced nucleation of the functionalized FWS and carbon enrichment on the muscovite surface subdued the K^+ -induced electric field and transformed the aggregate geometry.

In situ AFM images of the ternary mixture after equilibration with the mica surface (not treated with KCl) followed by the addition of 10 mM Ca^{2+} resulted in the growth of mound-like aggregates. The larger diffusion-limited mass transfer of particulates across the Ehrlich–substrate adhesion.

Schwoebel barrier (ESB) or step edge barrier contributed to the Z-directed growth of spiral mounds. Quadratic polynomial fitting of the clusters obtained at different time intervals after the introduction of Ca^{2+} demonstrated an increase in the sharpness of the parabolic curve and reduced curve planarity (Fig. 5). The undulating geometry of the parabolic curves indicated at the top, specifically approximately 30 min after Ca^{2+} addition, emphasized screw dislocation and transportation of particulates around the spiral core to higher steps.

Fig. 5 Quadratic polynomial fitting of the aggregate heights obtained from the ternary mixture of Na-KI, FWS, and TA at different time intervals after the injection of 10 mM CaCl_2 . The ternary mixture was equilibrated with mica for 120 min before CaCl_2 addition. Reduced 2-D nucleation, skinnier and sharper parabolic curves with high bow indicated deviation from the fitting with time. The screw-dislocation-driven spiral motion of particulates around the dislocation core facilitated the mass transfer of particles to avoid the steep Ehrlich–Schwoebel barrier (ESB); hence prompting the growth of a binary colloid crystal (Ghosh et al., 2019).

Electrical and magnetic force microscopy (EFM/MFM)

The versatility of scanning probe force microscopy (SFM) has application in mapping the surface potential or work function, and visualization of magnetic forces emanating from the materials. In these two-pass force microscopic systems, in the first pass, a topographic image is recorded from the short-range van der Waals force (in the order of r^{-6}) due to a non-contact mode rastering of the probe over the substrate surface at its resonance frequency. In the second pass, the probe rests at a specific height away from the surface and maps the long-range electric and magnetic fields (in the order of r^{-2}) with a change in phase angle. Briefly, the upward (repulsive) or downward (attractive) bending of the magnetic/electrical probe under the magnetic and electric fields emanating from the colloidal particles and nanostructures adhered to the substrate surface and consequent phase shift is interpreted as the deviation from the driving voltage signal and the actual displacement response of the cantilever (www.parksystems.com).

The evolution of MFM, EFM, and KPFM (electrical or Kelvin probe force microscopy) techniques has provided nanoscale-resolutions of materials that are unlikely to be obtained by any other means. Let us consider the equation of motion of an oscillating cantilever in the absence of any interaction with the substrate,

$$y_0 = A_0 \sin(\omega t \pm \varphi) = A_0 \sin(2\pi f_0 t \pm \varphi_1) \quad (1)$$

above a surface with a free amplitude A_0 , f_0 is the resonance frequency of the cantilever, ω is the angular velocity, t is the time, and φ is the phase angle. However, during interactions with the substrate, the free amplitude of the cantilever changes. In the case of attractive interactions, $f_0 > f$, while in the case of repulsive interactions $f_0 < f$ and the modified equation:

$$y_1 = A \sin(\omega t \pm \varphi_2) = A_0 \sin(2\pi f t \pm \varphi_2) \quad (2)$$

The phase difference is shown schematically in Fig. 6. The frequency shift allows direct measurement of the force changes, phase lag, and amplitude signals which are then combined to calculate the dissipation of energy in each oscillation cycle due to tip-sample interaction.

Enhanced electrical force microscopy or Kelvin probe force microscopy (KPFM)

The surface charge behavior of soil mineral particles plays a significant role in diverse geochemical processes including sorption of NOM on the mineral matrix, adsorption of contaminants, and colloidal transport through environmental media. Among the naturally abundant mineral particles, clay showed significantly complex surface charge behavior due to the isomorphous substitution and pH-dependent ionization of the edge groups. Several experimental techniques including electrokinetic measurements have been used to determine the electrical double layer (EDL) and surface charge behavior of kaolinite particles at a macro level. However, the asymmetric distribution of surface charge on clay particles requires the application of KPFM. The Kelvin probe technique, named after Lord Kelvin, who provided the concept of built-in contact potential difference in metals first observed by Alessandro Volta in the early 19th century. Let ϕ be the work function i.e. the minimum energy required to remove an electron from the ground state or in other words the difference in energy between electrons in a free state to that of those at the Fermi level (Palermo et al., 2006). When two capacitors composed of two different metals, with different work functions (WF) are electrically connected, electrons will flow from lower WF (ϕ_1) material to the material with higher WF (ϕ_2) because of greater electron binding capacity. The opposite charges on the capacitor plates and a contact potential difference (CPD) between the two materials can be identified. The presence of an electric field in the capacitor due to these charges can then be easily detected. An external potential V_c can be applied to nullify this field. At equilibrium, the field is zero, and the externally applied potential equals the contact potential difference, which corresponds to the difference between the two WFs (Fig. 6). Therefore, knowledge of ϕ_1 has shown the possibility of calculating ϕ_2 : $\phi_2 = \phi_1 - qV_c$ where q is the elementary charge. Lord Kelvin first realized this electron tunneling phenomenon while studying the interaction phenomenon between polished Cu and Zn surfaces with an electroscope measurement. However, Zisman (1932) improved the method by using a vibrating capacitor setup with mechanical oscillation at a specific frequency which induces a change in the capacitance of the system with the formation of a small alternating current. Therefore, with the discovery of AFM in the early 1980s, Nonnenmacher et al. (1991) applied the KPFM technique to determine the CPD between a sharp conducting probe and the surface. The CPD between the tip and sample is defined as $V_{CPD} = (\phi_{tip} - \phi_{sample})/-e$, where ϕ_{tip} and ϕ_{sample} are the work functions of the sample and the tip. For the actual measurement of CPD, an additional voltage is applied between the two plates until space in-between becomes field-free and the current goes to zero. The KPFM measures the potential difference by applying an AC voltage on the tip. The electrostatic force ($F_{ES}(z)$) is given by the equation:

$$F_{ES}(z) = -\frac{1}{2} \Delta v^2 \frac{dc(z)}{dz} \quad (3)$$

that originated from CPD between the tip and sample surface, and where z is the direction normal to the sample surface, Δv is the potential difference between V_{CPD} and the voltage applied to the AFM tip, and $\frac{dc(z)}{dz}$ is the gradient of the capacitance between tip and sample surface.

Application of phase imaging and KPFM and MFM

The electrical and magnetic properties of soil mineral particles provide a semi-quantitative estimate of material properties. The interfacial arrangement of clay particles on the air–water interface in the presence and absence of NOM depends upon the surface

Fig. 6 The detection of stray electric and magnetic fields in a two-pass mode. In the first pass, topographic images are recorded, and in the second pass at a specific lift height probes detect the electric and magnetic fields emanating from the particles or materials that caused a change in phase angle. Schematic diagram of the electron tunneling effect proposed by Lord Kelvin the foundation of the KPFM process. Based on Palermo V, Palma M, and Samori, P (2006) Electronic characterization of organic thin films by Kelvin probe force microscopy. *Advanced Materials* 18(2): pp. 145–164.

charge asymmetry of kaolinite particles. In situ AFM images of an Na–Kl and TA mixture at pH 7 in the absence of added cations showed the wire-like arrangements of particles as indicated in Fig. 7. The attainment of polarizability maxima and EDL repulsion minima facilitated such an arrangement. The surface potentials of Na–Kl and the heteroaggregate were determined by KPFM in a Bruker Multimode 8 AFM with an MESP-V2 KPFM cantilever (0.01–0.025 Ohm-cm antimony doped Si) with a spring constant of 3 N m^{-1} and a resonance frequency of 75 kHz in lift mode. Ex situ AFM height and corresponding KPFM images of Na–Kl at pH 7 also showed the tip-to-tip arrangement of kaolinite. Enhanced ionization of Si–OH groups on the tetrahedral facet of silicate (Si–Tr) and asymmetric surface charge at pH 7 and stronger EDL repulsion prevented the sideways approach of Na–Kl particles but led to a head-to-tail arrangement. A potential energy minimum can be attained at minimum EDL repulsions with maximum polarizability. Except for the interfacial arrangement of particles, the heteroassociation mechanism between Na–Kl and fullerene NPs in the presence of TA and Ca^{2+} showed 1-D screw dislocation-mediated growth of tubular structure. The surface potential map of the tubular structure revealed the generation of crystallographically oriented nearly linear nanopores with an average pore radius of $\approx 30\text{--}50 \text{ nm}$, produced from the screw dislocation-mediated shear with a concomitant rise in the Burgers vector. The KPFM height and corresponding potential contrast revealed the formation of a hollow core and movement of the mass from the tubular core i.e. dislocation motion. This is in line with the formation of GaN nanopipes. Frank (1951) explained that the strain around the

Fig. 7 (A) In situ AFM height images of tip-to-tip wire-like assembly of Na-KI in the presence of TA at pH 7 due to asymmetric EDL repulsion. Ex situ (B) AFM height and (C) KPFM surface potential of pure Na-KI particles at pH 7. (D–E) AFM height and corresponding KPFM images of Na-KI and FWS mixture in the presence of 2 mg L^{-1} TA and 10 mM Ca^{2+} at pH 7 revealed screw dislocation driven tubular growth. Ex situ AFM (F) height and corresponding (G) MFM image of Fe_3O_4 nanocluster. (H) AFM height and (I) MFM phase images of $\gamma\text{-Fe}_2\text{O}_3$ NPs. It is evident from these images that the magnetic phase shift is lower from the larger Fe_3O_4 NPs clusters relative to smaller clusters of $\gamma\text{-Fe}_2\text{O}_3$ NPs (darker color). Notably in both the MFM images the magnetic field emanating from the smaller clusters was much weaker than larger clusters. The images were taken at a constant lift height of 30 nm (Ghosh et al., 2014, 2019; Guo et al., 2020).

screw-dislocation and high Burgers vector enable particulate movement next to dislocation sites to reduce strain and showed that the Burgers vector (B) for the formation of hollow cores is:

$$B > \frac{66\pi\gamma}{\mu} \quad (4)$$

where the surface energy (γ) is 0.4 J m^{-2} and the elastic modulus (μ) $\approx 4 \text{ G Pa}$ for kaolinite. Adding in these values showed that the right-hand side term must be $>20 \text{ nm}$ for a hollow core to be formed in the tubular aggregates. The average estimated pore radius (r) for the tubular cores determined from the following equation was found to be $\approx 50 \text{ nm}$:

$$B^2 = \frac{8\pi^2\gamma r}{\mu} \quad (5)$$

The AFM images of the sample showed pore radii within the range of $30\text{--}50 \text{ nm}$, which are consistent with the calculated value.

The natural abundance of magnetic NPs and synthesized nanoscale zero-valent iron (nZVI), which are effective in the remediation of contaminated groundwater requires their delivery to contamination sites. The magnetic dipolar force-mediated aggregation of the particles and consequent loss of reactive surface area reduces their efficacy toward the degradation of contaminants including chlorinated compounds. The application of MFM, a semi-quantitative technique has shown strong efficiency in determining the stray magnetic field emanating from magnetite NPs (Magnetic Force Microscopy (MFM), n.d.). The MFM imaging of these nanoclusters has determined the 'Z'-directed stray magnetic field with a magnetized 45 nm Co—Cr (cobalt—chromium) alloy-coated silicon MFM tip (MFM, Asylum Research, USA). The application of MFM has shown enormous potential in identifying the magnetic domains in NPs or nanostructures. The TMAFM height image of magnetite NPs and head-to-tail alignment of the magnetic dipole showed the formation of magnetic nanowire on a mica substrate. To identify the difference in magnetic field that emerged from Fe_3O_4 (magnetite) and $\gamma\text{-Fe}_2\text{O}_3$ NPs, MFM measurements at a constant lift height of 30 nm indicated a weaker magnetic phase shift from the larger clusters of Fe_3O_4 NPs relative to the smaller dimensional $\gamma\text{-Fe}_2\text{O}_3$ NPs maintained at pH 6 (Fig. 7F–I). It is likely that despite the larger dimension of the Fe_3O_4 NPs cluster, the size of the individual magnetite NPs was less than the individual $\gamma\text{-Fe}_2\text{O}_3$ NPs (darker color, stronger phase shift) referring to greater thermal fluctuations and loss of magnetic moments. The darker phase-contrast corresponding to the larger negative magnetic phase shift is attributed to the stronger attractive magnetic dipolar force between the magnetic probe and the NPs. But Fe_3O_4 NPs with a larger surface to core ratio and enhanced surface defects, and oxygen-mediated loss of surface magneto-crystalline anisotropy that contributed to the magnetization loss. The advantage of MFM relies on the fact that instead of measuring the actual magnetic moments it can provide a semi-quantitative estimate of the nanoparticle's magnetic strength. Because the determination of magnetic moments in a superconducting quantum interference device (SQUID) is very expensive because of the need for liquid helium. Therefore, MFM can be useful in estimating the magnetic moments of nanostructures as well as deciphering the mobility of magnetic domains.

Colloidal probe force microscopy (CPFM) and DLVO interactions

The DLVO forces or surface forces, a summation of van der Waals attraction and electrostatic double layer (EDL) repulsion, determine the interparticle interaction forces specifically for inorganic colloidal particles. In a high dielectric aqueous medium, the mutual interactions between the EDLs result in strong repulsion due to ionization of the surface functional groups. Mathematically, the electrostatic repulsive force (F_{el}) is defined as (Butt et al., 2005):

$$F_{el} = \frac{4\pi R \sigma_1 \sigma_2}{\epsilon \epsilon_0 \kappa} e^{-\kappa D}, \quad (6)$$

$$\kappa = \sqrt{\sum_i \frac{n_{i\infty} e^2 z_i^2}{\epsilon \epsilon_0 kT}}, \quad (7)$$

where F_{el} as a function of distance D for a probe and has been normalized by the sphere radius (R). Since $F/2\pi R$ is equal to the energy per unit area between two equivalent flat surfaces, σ_1 and σ_2 are the surface charge densities of the two surfaces, ϵ_0 is the permittivity of free space, ϵ is the dielectric constant of the solvent, κ^{-1} is the Debye length determined from the salt concentration; $n_{i\infty}$ is the bulk concentration of the ion species i ions per unit volume, z_i denotes the valency of that ion species. The sum runs over all ionic species present, e is the unit charge. Typical force curve measurement data were obtained for a silica probe and silica surface at different ionic strengths, and curve-fitting determined the Debye length from the F vs D curves. However, at higher ionic strengths and pH near the point of zero charges (PZCs), the van der Waals attraction (VdW) between the colloidal probe and substrate originated from the dipole–dipole, and dipole induced dipole interactions become dominant. The van der Waals force is calculated from Lifshitz theory based on quantum electrodynamics and spectroscopic measurements. For a sphere of radius R interacting with a plane, the VdW force is given by:

$$V_a = -\frac{HR}{6D^2}, \quad (8)$$

where H is the Hamaker constant and depends on the dielectric properties of the interacting materials and the medium in between. The van der Waals force is usually attractive with very few exceptions. In CPFM, between inorganic surfaces except for DLVO interaction, colloidal probes experience an extra hydration repulsion force at smaller probe–substrate separation with a probable steric or entropic origin. However, the evaluation of hydration forces is often misconstrued with the roughness of the substrate because the range of surface forces has the same order of magnitude as the surface roughness. Conversely, at long-range probe–substrate separations, a hydrodynamic drag force also originates from the speed of colloidal probe movement during the approach toward the substrate surface (Fig. 8).

Fig. 8 A schematic diagram of probe–substrate interactions and deflection of the cantilever in repulsive and attractive regimes. Three different models of probe–substrate adhesion mechanics. SEM and optical microscopy images of the colloidal silica probe. Based on Butt H-J, Cappella B, Kappl M (2005) Force measurements with the atomic force microscope: Technique, interpretation and applications. *Surface Science Reports* 59(1–6): 1–152 and Israelachvili J (2011) *Intermolecular and Surface Forces*. Amsterdam: Academic Press.

Experimental setup

The experimental setup for CPM was first introduced by [Ducker et al. \(1991\)](#), where the sharp AFM tip is replaced by a spherical or quasi-spherical colloid particle of microscale dimensions including silica, glass, iron oxide, and polystyrene beads. The bead is fixed to the tipless cantilever with epoxy glue aided by a micromanipulator followed by measurement of the spring constant with thermal tuning of the probe. At large separations where the interactions between the probe and substrate are minimal, the cantilever deflection is small. However, at a specific probe–substrate separation, when cantilever deflection results from an interaction between the probe and sample, the change in separation is a combination of static deflection and piezo displacement. At smaller distances, a repulsive force acts between the tip and sample, and the cantilever bends upward. The tip and sample are not in contact, therefore, this region is often referred to as the noncontact region. In the case of attractive interaction energy, the force gradient exceeds the spring constant resulting in spring instability and the two surfaces accelerate toward each other. Cantilever deflection is measured by the optical lever technique, first a beam from a laser diode is focused onto the end of the cantilever and the position of the reflected beam is monitored by a position-sensitive detector (PSD). The reverse-side of the cantilever is usually covered with a thin layer of gold to enhance its reflectivity. When a force is applied to the probe, the cantilever bends and the reflected light beam moves through an angle equal to twice the change in the end slope $\tan \alpha$ ([Butt et al., 2005](#)). For a cantilever with a rectangular cross-section of width w length l and thickness h the change in the endslope is

$$\tan \alpha = \frac{Fl^2}{2E_c I}, \quad (9)$$

where E_c is the elastic modulus of the cantilever, and $I = \frac{wh^3}{12}$ is the moment of inertia.

If the detector is at distance d from the cantilever and with a small deflection of the cantilever if the laser moves a distance of m , then

$$m = 2d \tan \alpha = \frac{Fl^2}{E_c I}, \quad (10)$$

the distance d away from the cantilever, for a small cantilever its deflection is given by:

$$\Delta z_c = \frac{Fl^3}{3E_c I} = m \frac{l}{3d} \quad (11)$$

Except for the DLVO forces, the abundance of NOM in the soil can significantly affect interparticle interactions. The molecular conformation of the biomolecules adheres to either substrate or the probe under compression between the approaching surfaces, and can induce long-range electrosteric interactions. The confinement of the adsorbed polymer between the probe and the substrate, and their large radius of gyration of the adsorbed polymeric chains provide an entropic contribution or steric force ([Biggs, 1995](#)).

The underlying principle of measuring adhesion force by AFM is based on the principles of 'contact mechanics' first proposed by Hertz, where the interaction force is purely repulsive on contact. However, Johnson, Kendall, and Roberts (JKR) accounted for the theory of adhesion between two elastic bodies where experimentally measured contact areas were larger than that proposed by Hertzian interactions, specifically at low loads or zero applied load. Derjaguin–Muller–Toporov (DMT) also derived a separate expression to include adhesion in the contact of elastic bodies, where the contact profile remains Hertzian and the attractive forces act like an additional external load ([Israelachvili, 2011](#)). The contact mechanics in the JKR model is a short-range adhesion force, whereas the DMT model represents a long-range surface force. The differences between these two models were resolved by Tabor who had pointed out that both the JKR and DMT models are at opposite ends of the same spectrum ([Johnson and Greenwood, 1997](#)). Experimentally, the actual adhesion mechanism between the elastic probes and the substrates follows the Lennard Jones potential (V_{LJ}) a weak form of van der Waals attraction according to the following equation ([Israelachvili, 2011](#)):

$$V_{LJ} = 4\varepsilon \left[\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right], \quad (12)$$

where V_{LJ} is the intermolecular potential between the two atoms or molecules. ε is the potential well depth and a measure of how strongly the two particles attract each other, σ is the distance at which the intermolecular potential between the two particles is zero, and r is the separation distance between the centers of the interacting particles.

Application of CPM techniques

The environmental mobility and groundwater transport of colloids, adhesion of structurally different particulates, attachment of bacteria to mineral substrates, and stable soil aggregate formation depend on surface forces. The pore water chemistry including pH, ionic strength, and molecular makeup of the NOM molecules play a key role in interparticle interaction prevalent in unsaturated soil. The CPM was successfully applied to evaluate the variation in EDL repulsion between a colloidal silica probe and silica substrates with variation in surface density of the silanol groups ([Butt et al., 2005](#)). Stronger EDL repulsion with a spherical silica probe was recorded for a substrate with a 10° water contact angle relative to the substrate surface with a 45° contact angle. Therefore, this emphasizes the role of nanoscale interactions in the macroscopic properties of mineral substrates.

The interaction forces between a colloidal silica probe with silica and mica substrates have significant implications the coherence of soil mineral particles, essential in primary soil aggregate formation ([Wang et al., 2021](#)). Previous macrolevel studies have shown the importance of sesquioxide minerals as cementing agents in stable soil aggregate formation. In this context, interaction of the

colloidal silica probe with naturally occurring amorphous iron oxyhydroxide (FeOOH), and hematite-modified silica and mica substrates showed strong pH-dependence regarding probe–substrate adhesion. Our recent investigation on colloidal forces between a silica probe and small-sized hematite NPs layer-coated mica (Hm-mica) substrates in the presence of 5 and 50 mg C L⁻¹ with carboxylate-rich HA and phenol-rich TA, and alkaline earth metal ions and the organic guanidinium cation (Gd⁺[(NH₂)₃C⁺]) revealed the relative adhesion efficiencies regarding the coherence of soil mineral particles. In the absence of cationic species, the high surface charge density of the ionized low pK_a carboxylates in HA, isolated from the Amherst peat soil encapsulating the HA-modified Hm-mica contributed to long-range EDL repulsion with the silica probe as seen from the approach curve. However, the lack of ionized carboxylate moieties in TA showed reduced probe–substrate repulsion. The weakly hydrated alkaline earth metal ions induced charge screening and minimized the long-range EDL repulsions between the probe and the substrate and eventual ‘jump-to-contact’ due to attractive van der Waals force (Fig. 9). Screening of the EDL charge in HA-modified Hm-mica followed the order Mg²⁺ < Ca²⁺ < Sr²⁺ < Ba²⁺, in the reverse order of hydrated ionic radius. The retract curves exhibited ion-specific interactions-mediated charge screening by the weakly hydrated cations and possible formation of a ‘pinned micelle’ with exposed hydrophobic domains, which contributed minimally to adhesion with the silica probe (Wang et al., 2021).

Unlike carboxylate-rich HA, weakly hydrated alkaline earth metal ion-mediated polarizability of the π -electron cloud in phenol-rich TA and the formation of a porous hydrogel-like structure that maintains interfacial water holding capacity contributed to the strong adhesion with the silica probe. The weak adhesion between silica probe and HA-modified Hm-mica in the presence of alkaline earth metal ions showed significant improvement in adhesion in the presence of the organic Gd⁺ cation. Barely hydrated Gd⁺ interactions with ionized carboxylate and the formation of salt bridges with hydrogen bond donor-acceptor interactions and the formation of water-enriched hydrogel-like structures contributed to the probe–substrate adhesion (Fig. 10).

The interfacial porous nanotubular structures produced from HA interactions with Gd⁺ determined from the AFM height imaging also supplemented the AFM force data. Therefore, ion specificity of the cationic species, the concentration of NOM molecules, and the formation of novel nanostructures with enhanced water holding capacity may contribute substantially to soil aggregate stability against destabilizing shear forces during slaking.

Biologically active CPM has been used to measure the interactions quantitatively between *Shewanella oneidensis* (a dissimilatory metal-reducing bacterium) and goethite (α -FeOOH), both commonly found on Earth in near-surface environments (Lower et al., 2001). Biologically active force probes are prepared by attaching bacterial cells to a colloidal bead to the end of a silicon nitride cantilever. The force–distance curves between the probe and mineral surface under aerobic and anaerobic conditions have shown that the affinity between *S. oneidensis* and goethite rapidly increased under anaerobic conditions due to electron transfer from the bacterium to the mineral surface. The worm-like chain (WLC) model fitting in the adhesion force data revealed that the outer membrane of *S. oneidensis* specifically interacts with the goethite surface facilitating electron transfer.

The results of the adhesion forces data using CPM need to be judged carefully. Both the roughness of the probes and substrate surfaces specifically at higher loading caused sticking of the probe to the substrate surface. The first contact of the probe with any roughness on the hard substrate and topographic inhomogeneity determines the ‘zero distance’ and creates a potential wall during retraction of the probe; therefore, this affected the plausibility of the colloidal probe data. Butt et al. (2005) suggested reporting the root mean square (RMS) roughness of the substrate surfaces, but also cautioned that it may not be an absolute measure and could sometimes be misleading.

Chemical force microscopy (CFM) and dynamic force spectroscopy (DFS)

Intermolecular interactions are critical in the molecular conformation, adhesion, and sorption behavior of soil organic matter (SOM) on the mineral–water interfaces. The potential energy landscapes of intermolecular interactions can be effectively determined from the interactions of the harmonic oscillator available in tiny springs attached to the AFM cantilevers together with other techniques including bioforce probes and or optical traps. The seminal work by Bell on the kinetics of forced bond rupture by applying the external force or loads based on the exponential amplification theory of Kramers (1940), which states that the shuttling action of Brownian motion can set free a particle from the potential energy barrier and create a transition state, thereby a method for calculating the rate of a chemical reaction (Friddle et al., 2008 and references therein). Evans and others had proven that the force required to rupture an adhesive bond depends upon the loading rate and shape of the interaction potential. Therefore, measuring the bond rupture forces over a range of loading rates is termed dynamic force spectroscopy (DFS). With the absolute force resolution in AFM, it is feasible to probe individual molecular interactions.

In DFS spectroscopy, a functionalized AFM probe is allowed to interact with a substrate until a bond is formed followed by pulling out of the cantilever from the surface until the bond is broken. In DFS, probes rupture forces under two different regimes specifically: (a) at a large range of pulling velocities, which explores bond rupture dynamics in a near-equilibrium regime i.e. stochastic, and (b) in a non-equilibrium regime with strong rates of pulling. Both DFS and CFM have been useful to probe nanoscale forces at the pN level. Nevertheless, CFM differs from DFS because in the former rupture forces occur at a single pulling velocity. A general perception about these techniques can be viewed from the difference between a harmonic and anharmonic potential energy diagram defined from the Morse potential (Fig. 11) (Friddle et al., 2008). The ratio of the rates of inherent binding to unbinding in equilibrium states provides information about the efficacy of bond formation against thermal fluctuations-driven bond breaking. In contrast, in a non-equilibrium regime bond-breaking becomes deterministic. Sand et al. (2017) indicated that a systematic variation in the rate of loading ($\dot{r}$) could be used as an analytical function for mean rupture force vs rates of loading to

Fig. 9 The approach curves of a silica probe and (A–C) HA-modified, (D–F) TA-modified hematite-coated mica (Hm-mica) substrates in the presence of different concentrations of Mg^{2+} , Ca^{2+} , and Ba^{2+} . The large carboxylic content in HA contributed to stronger repulsive interactions between the silica probe and substrate relative to TA-modified Hm-mica in the absence of any added electrolyte (Wang et al., 2021).

determine the behavior of biopolymer adhesion with mineral substrates. A molecular picture of the soil was obtained from quantification of the organo–mineral binding by Newcomb et al. (2017) using DFS spectroscopy. Briefly, DFS measurements were carried out between Au-coated AFM probes functionalized with -COO^- , PO_4^{3-} , NH_3^+ , and CH_3 groups and 001 faces of muscovite mica, and the 010 faces of goethite at varying rates of loading to estimate the binding strength between model organics and minerals, (Newcomb et al., 2017). A similar approach to force measurement was applied earlier in determining the adhesion behavior of biomineralized nacre, mother of pearl, where long titin protein molecules were attached to the AFM probe forming the molecular spring (Smith et al., 1999).

Concluding remarks

To understand the natural soil environmental processes requires an evaluation of the nanoscale phenomena occurring on environmental interfaces. The generality of AFM applications and its nanoscale resolution has shown enormous benefits in understanding the geochemical process to contaminant dynamics. The AFM has shown significant utility in identifying the bacterial adhesion to mineral substrates to NOM-assisted interfacial transformation of engineered nanomaterials and heteroassociation with soil mineral colloids. In addition, the role of solution chemistry and subsequent alteration in biomolecular conformation on the contaminant dynamics were determined unequivocally with AFM. Furthermore, the effect of mineral substrate surface symmetry and exchangeable cation-assisted electric dipole on the growth geometry of the self-assembled colloid crystals can be elucidated with AFM. In addition, the dislocation-driven epitaxial growth of colloidal crystals ascertained from force microscopic techniques can be extended to identifying the complex biomineralization processes occurring in soils and sediments. Furthermore, the determination of nanoscale forces with AFM to the coherence of soil mineral particles enriches our understanding of soil aggregate formation and empowers us to meet the imminent environmental challenges.

Abstract

Nuclear Magnetic Resonance (NMR) is a powerful analytical tool with the ability to not only identify chemical structures, but to examine non-covalent interactions in soils. Here, a range of modern NMR techniques is examined and their potential for soil research is summarized. In addition, a brief description of the pertinent theory and sample preparation, along with examples from the literature and practical experimental considerations is presented. The overall goal is to provide an overview and showcase of the strengths and capabilities of NMR, which is accessible to specialists and non-specialists alike.

Key points

- Provide a brief background of NMR Spectroscopy
- Summarize the wide range of NMR experiments available
- Provide an overview of sample preparation
- Address NMR in solid, gel, liquid and multi-phase samples
- Cover NMR in terms of both structure elucidation and non-covalent interactions

Introduction

Whether used to identify unknown compounds in a soil extract, examine the carbon profile of a dried soil, or study interactions between soil and pesticides, nuclear magnetic resonance (NMR) is a powerful analytical tool for the study of soils. When applied to its full potential, NMR can not only give an unparalleled understanding of the composition and structure of soil, but is arguably the most powerful method for studying non-covalent interactions such as aggregation and both covalent/non-covalent soil-contaminant binding. This is an increasingly important area of study, as an understanding of contaminant binding is essential to the understanding of long-term soil fertility, contaminant fate/transport, as well as developing the most effective remediation strategies. There have been numerous reviews addressing the application of NMR to soil research (Kögel-Knabner, 1997; Simpson et al., 2011; Cardoza et al., 2004; Mao et al., 2017; Simpson and Simpson, 2014), as well as some introductory feature articles (Simpson et al., 2012, 2018). Here we do not aim to provide a comprehensive literature review, but to explore and describe the

power of NMR for soil research from a practical perspective. We will focus on the wealth of NMR techniques available and their applications to soil research through the use of literature examples, with the goal of making the NMR of soil more accessible.

A brief explanation of nuclear magnetic resonance

Prior to a discussion of the potential and specifics of NMR as a tool for the study of soils, it is helpful to lay a groundwork for understanding NMR. A rigorous explanation of the theory behind NMR cannot be done justice in a few paragraphs, nor is it fitting with the ethos of making NMR accessible and thus will not be attempted here. Instead, we aim to provide a baseline explanation of NMR phenomena, which may help in understanding the requirements for a successful NMR experiment.

In contrast to most common spectroscopy techniques which involve electrons, NMR is based on the difference in energy between spin states of the nucleus in the presence of a magnetic field. A prerequisite for any NMR experiment is that the desired nucleus of study must have a nuclear spin. Fortunately, elements such as hydrogen, carbon, nitrogen, phosphorous and fluorine which are common in soil samples (and contaminants/agrochemicals) all have spin active stable isotopes (specifically ^1H , ^{13}C , ^{15}N , ^{31}P and ^{19}F). When a magnetic field is present, a nucleus with non-zero spin can align with the magnetic field, resulting in a lower energy state, or against the magnetic field, resulting in a higher energy state. This energy splitting is known as the Zeeman effect and the energy difference between these two states is exploited in the NMR experiment. On average, slightly more nuclear spins are aligned with the field than against it, creating a net magnetization, which can be manipulated by pulsing the sample with radiofrequency (RF) energy. Manipulation of the sample's magnetization forms the basis for all NMR experiments, ranging from simple 1-D experiments to complex multinuclear multidimensional NMR. Using RF pulses, the magnetization can be "flipped" from its equilibrium position (aligned with the external magnetic field), into a plane perpendicular to the magnetic field, where it can be detected. After this flip, the magnetization, like a spinning top that is pushed off axis, begins to precess around the magnetic field. The frequency of this precession is known as the resonant (or Larmor) frequency and is unique to the chemical environment of the nucleus. The sensitivity of the resonant frequency with respect to changing chemical environments is precisely what makes NMR a powerful tool for both identifying chemical structures and examining non-covalent interactions.

Common nuclei in NMR

Prior to examining the differences between the types of NMR, the nucleus under study is important to consider as it determines the type of information resulting from the experiment as well as the difficulty and length of the experiment. In general, ^1H is by far the most commonly studied nucleus due to its excellent NMR sensitivity (of note, ^1H is used in the vast majority of studies in the solution-state, but is rarely used for solid-state analysis as dipolar couplings lead to very broad and often unresolvable spectra). In the solid-state, ^{13}C is the most commonly studied nucleus. When considering the use of NMR to study a specific nucleus, there are many factors to consider: the gyromagnetic ratio, natural isotopic abundance, nuclear spin (i.e., spin $\frac{1}{2}$ or quadrupolar), relaxation time and spectral dispersion. The gyromagnetic ratio is an inherent property of a nucleus and the NMR signal scales with this value to the third power (Webb, 2012). Thus, considering only this factor, ^{13}C already gives ~ 64 times less signal than ^1H . However, natural abundance, which describes the proportion of the specific nucleus found in natural samples, is also an important factor. For ^1H , the natural abundance is $\sim 99.99\%$, whereas for ^{13}C it is only $\sim 1.1\%$, further making ^{13}C ~ 2 orders of magnitude more difficult to study. Overall, the receptivity of ^{13}C at natural abundance relative to ^1H is $\sim 0.02\%$ (Harris et al., 2001). That said, difficult does not mean impossible and modern NMR techniques are commonly used to study carbon in whole soils, though these experiments are much longer than proton studies. The ^1H , ^{13}C and ^{15}N nuclei make up the vast majority of soil NMR studies, but research has been done on other nuclei such as ^{19}F , ^{31}P and other more niche nuclei including various metals, silicon and deuterium (Simpson et al., 2011). With regard to the nuclear spin, nearly all nuclei studied in soils have a spin of $\frac{1}{2}$. This is beneficial as compounds that have a spin greater than $\frac{1}{2}$ (known as quadrupoles) possess electric quadrupole moments which interact with nuclear spins, leading to significant spectral broadening and overlap. This can often make spectra very difficult to interpret and is the main reason that ^{15}N is studied (0.137% abundance) compared to the much more abundant, but quadrupolar ^{14}N ($\sim 99.6\%$ abundance). The values for gyromagnetic ratios and abundances quoted here are sourced from the IUPAC recommended values, as outlined in the work by Harris et al. (2001).

Another factor that affects the time required for analysis is the relaxation time, which changes with both the nucleus studied and the sample itself. In simple terms, after each RF pulse and data acquisition, some time must be allotted to allow the spins to relax to the equilibrium state. This time is known as the recycle delay and limits the rate at which experiments can be repeated. Since NMR is inherently insensitive, signal averaging is central to NMR experiments, and, crucially, is linked to the recycle delay. The greater the number of "scans" (or transients) that can be acquired per unit time, the greater the signal to noise ratio (SNR). Specifically, the SNR scales with a factor of $n^{1/2}$, where n is the number of scans. Especially in environmental mixtures such as soil, many scans (for example 50,000 for ^{13}C analysis) can be required to analyze samples, and thus shorter relaxation times are typically beneficial. Properties of the sample such as the solvent or presence of paramagnetic species (e.g., iron, oxygen) have significant effects on relaxation time. That said, relaxation times in environmental samples (e.g., soils, water samples) tend to be substantially lower than for small molecules (e.g., organic chemistry samples), and it is important to ensure that the recycle delay matches the relaxation time of the sample to ensure the optimal SNR. The nucleus studied also has a significant impact on the recycle delay and ^1H tends to have

much shorter relaxation times compared to ^{13}C and ^{15}N , though the value of the latter can be decreased by the addition of a relaxation agent such as chromium(III) acetylacetonate.

Choosing a nucleus

Given the factors discussed above, it seems easy to conclude that ^1H NMR is simply better than ^{13}C or ^{15}N NMR. While in terms of ease of experiment, this is probably the case, it is not the whole story. First, it is important to note that these analyses give different information. For example, quaternary carbons cannot be detected directly by ^1H NMR. Further, both ^{13}C and ^{15}N benefit from significantly improved dispersion, as the chemical shift is spread over >200 ppm, whereas ^1H chemical shifts typically do not extend past ~ 12 ppm. In ^{13}C spectra, due to the rarity of these nuclei at natural abundance (as well as ^1H decoupling), there is virtually no splitting, leading to less spectral overlap, and less complex line shapes than ^1H experiments. This of course begs the question: “which nucleus should be used to study soils?” While the answer is unique to the research question at hand, a few general recommendations can be made.

For solution-state NMR, ^1H is the easiest to implement and thus its use would be prudent, providing it addresses the research question. In addition, a range of “inverse detected” 2-D solution-state experiments exist (see section on multidimensional NMR) that retain sensitive ^1H detection, but, if used to their full potential, can provide information on all carbons indirectly (including quaternary carbons). However, if the analysis is in the solid-state, ^{13}C NMR is recommended, given that ^1H in the true solid-state is relatively uninformative. For an excellent review on solid-state ^{13}C NMR of soils, see the work by Preston (Preston, 2001). Due to its difficulty, ($\sim 2\%$ of the receptivity of the already challenging ^{13}C) ^{15}N NMR is recommended only when information on nitrogen is the major focus of the research work.

Two other nuclei are of note: ^{19}F , which possesses excellent sensitivity ($\sim 80\%$ of ^1H) and ^{31}P which has moderate sensitivity ($\sim 7\%$ of ^1H). These are recommended if the research question specifically involves compounds that contain these atoms. For example, ^{19}F has been used to study the interactions of fluorinated compounds with soil (Masoom et al., 2015), and ^{31}P can be used to examine phosphorus speciation and cycling (Vestergren et al., 2012). As a final note, there are several multidimensional NMR techniques which can involve multiple nuclei and can be very useful to enhance dispersion and elucidate chemical structures. These are discussed in the multidimensional NMR section.

An overview of different NMR techniques

Though classically NMR analysis could only be carried out in either the solid (i.e., a dry soil) or solution-state (e.g., a soil extract), recent developments in NMR technology have allowed much greater latitude in sample preparation and analysis. A general outline of the broad types of NMR techniques is given in Table 1. In soil research, the most commonly used forms of NMR are solid-state NMR, followed by solution-state NMR. Here we will discuss and provide examples of the various NMR techniques used to study soils. Sample preparation for solution-state NMR is very different from the other major techniques (solid-state, high-resolution magic angle spinning (HR-MAS) and comprehensive multiphase (CMP) NMR) and these will be discussed separately.

Preparing the NMR experiment

In common with any analytical technique, there are a number of factors that must be addressed to obtain high quality spectra, and will be discussed here. For more detail on experimental preparation, see Simpson et al. (2011). Though most of these processes were once done by hand, modern spectrometers tend to have automated programs to perform these steps, and, if available, this is generally recommended. After placing the sample in the spectrometer, it is critical to wait for the temperature to stabilize prior to starting experiments (ideally before shimming), as this can help reduce temperature induced spectral drift and helps ensure reproducibility. Once a sample is stable in the spectrometer, a spectrometer lock (if available) should be performed, typically on a deuterated solvent. The spectrometer lock helps to adjust for magnetic field fluctuations, giving more reproducible spectra with sharper line shapes. This is especially important for long experiments since the risk of field drift becomes larger with time. After locking, the sample should be shimmed to obtain improved line shape. Shimming involves adjusting the current through smaller electromagnets around the central magnet to homogenize the magnetic field in the sample region as much as possible, which gives rise to optimal line shape. This is a crucial step and proper shimming can be the difference between a broad, relatively uninformative profile (i.e., badly shimmed) and an information rich profile potentially containing 1000 s of partially resolved peaks (well shimmed). Over the years, shimming (especially for solution-state experiments) has improved dramatically and modern gradient-based shimming methods are highly recommended, if available.

Calibrating the pulse length is an important factor and one that greatly influences the SNR. If the pulse length is not set correctly, the SNR of the entire experiment can suffer significantly. In natural samples it is not uncommon to see differences up to 100% in pulse length between samples, (Simpson et al., 2011) and not calibrating for such a change could result in cutting the SNR in half. Thus, it is imperative to calibrate the pulse length on a per sample basis. This can be done via an automated process on most modern spectrometers or by incrementing increasing pulse lengths and selecting the one that gives the largest SNR (or $1/4$ of the null at the

Table 1 A brief description of modern NMR techniques.

Technique	Description	Comments
Solution-State NMR 	Provides highest resolution but only for soluble components. The approach is fully quantitative if collected under appropriate conditions. For samples with low salt cryogenically cooled probes can increase signal to noise. Both helium and nitrogen cooled versions are available. For samples with high salts using a small diameter room temperature probe (1 mm or 1.7 mm) instead of a cryoprobe is a good option.	Probes range from 1 mm (5 μL) to 10 mm (4 mL) in size with 5 mm (600 μL) the most common. For a 5 mm cryoprobe, the detection limit for individual compounds is in the ng range, but as environmental mixtures can contain a large number of components 50–100 mg is recommended (1D and 2D NMR). Smaller probes are ideal when sample is mass limited. For mass-limited samples 1–3 mg is possible with a 1.7 mm probe. Only use a 1 mm probe when there is <1 mg sample.
Solid-State NMR 	Important for environmental analysis as it provides an overview of the types of carbon in a sample. This sample is spun at magic angle (54.7°) to narrow line shape and high power ^1H decoupling is required to improve carbon lineshape. The technique can be quantitative but considerable care must be taken if absolute quantification is required.	4 mm rotors are the most common and spin up to 15kHz. 4 mm rotors often require 80–120 mg of sample. 7 mm rotors hold ~400 mg of sample and thus can give more signal. However, RF homogeneity reduced and max spinning speed only ~7 kHz. Sidebands appear in solid-state NMR, they can be either moved out of the spectral window by spinning fast enough or can be suppressed using various methods such as TOSS.
High Resolution Magic Angle Spinning NMR 	This technique invented in 1996 combines magic angle spinning with a lock and magic angle gradient. Sometimes called “gel-phase” NMR, the approach allows swollen components to be studied with resolution similar to that in the solution state. When using ^1H both true solutions and swollen components are detected but true crystalline solids are not (the approach uses low power electronics and therefore cannot decouple the strong ^1H—^1H dipolar interactions in crystalline solids).	The approach has huge potential for study of soils, plants, air-particles and even small organisms in their swollen state. Samples can be either swollen in the rotor (for example soil + water) or put in whole with the natural water as acting as the solvent (i.e., a piece of carrot). Provides information on moieties swollen by water. In soil for example the approach highlights the all-important soil-water interface. As with solid-state NMR rotors are used, but with additional liquid seals. In general solution state NMR experiments are used in HR-MAS studies.
Comprehensive Multiphase NMR 	Introduced in 2012, CMP combines solids and solution state NMR. The approach can be thought of as a HR-MAS probe with the added ability to handle high power and therefore perform solid-state experiments. As such the probe can access <i>all components</i>, liquids, gels and solids in a sample. When applied to samples in their swollen state it provides a unique insight into conformation and structure in the natural state.	Key technique to follow processes that involve solids, being converted into liquids or vice versa. Examples include, flocculation, swelling, drying, growth, reactions, conformation change or sequestration of a liquid contaminant. For studies looking at non-dynamic multiphase systems combining a HR-MAS and solids probes will give similar results to CMP. However for dynamic systems (components dynamically changing phase) a CMP probe is ideal.
Hyphenated NMR 	Becoming commercially available in the 1990's, the approach combines separation with NMR. The most common setup being HPLC-NMR. More advanced setups also integrate SPE (for concentration) and MS. In principle, one can acquire NMR spectra (provides connectivity) and mass spectra (provide molecular formulae) to solve specific unknowns de-novo.	In practice for complex environmental samples, neither MS or NMR are the limitation, with the separation being the bottleneck. For example, in a recent 2D HPLC-NMR study of DOM even after fractionation into 10,000 fractions each still contained 100's of molecules making them too complex for the assignment of exact structures by MS or NMR. Hyphenated NMR is currently best used for non-targeted screening of less complex matrices, such as waste water or identification of targeted unknowns within mixtures.

Table 1 (Continued)

Technique	Description	Comments
Low field NMR 	Low field NMR encompasses many areas including mobile NMR and field cycling. Field cycling maps the relaxation times across a range of field strengths and provides novel information on dynamics. Portable NMR includes low field instruments that largely reproduce higher field NMR experiments but at low field and in a greatly reduced size and cost format. Specific instruments such as well loggers provide relaxation information can then identify the quality and existence of crude oil deposits.	Low field NMR has considerable potential for environmental research. Once purchased, low field NMR units based around permanent magnets require only a power supply to operate. Currently monitoring sites under remediation is extremely costly and can involve daily, weekly or monthly sampling combined with GC-MS and/or LC-MS analysis. If mobile NMR could be used in some of these applications it could greatly reduce cost as well as providing complimentary and real-time monitoring. The drawback is the reduced resolution and sensitivity over higher field instruments.
Magnetic Resonance Imaging	While spectroscopy focuses on chemical environments of nuclei within a sample, imaging produces visual images based on the water distribution within the sample. MRI is appealing as it provides a visual overview and internal structure that is inaccessible to most techniques.	MRI has huge potential to monitor and quantify larger scale processes such as contaminant transport, water swelling and provide key information on pore sizes and dynamics. It is also possible to perform localized spectroscopy in MRI.

360° angle). Of note, in experiments that use multiple pulses, for example 2-D NMR or more complex 1-D experiments, pulse calibrations are even more essential. In such cases, a mis-calibrated pulse does not just produce smaller SNRs, but incomplete spin flips, meaning that the desired interactions (coherences) do not form and the experiments essentially fail to produce the desired signals.

The receiver gain, which determines the “sensitivity” of the receiver is another important factor. For challenging and dilute samples, the gain must be set to the maximum for optimal SNR. That said, a particularly large peak (usually due to a non-deuterated solvent) may “overflow” the receiver, degrading the spectrum and this can be avoided by decreasing the gain until the overflow no longer occurs. The final factor that will be discussed here is the recycle delay. This is the time required between scans to allow the spins to relax to equilibrium. The relaxation time can be found from an inversion recovery experiment (see the quantitative NMR section), but for qualitative or semi-quantitative spectra it is common to use a shorter recycle delay.

Solution-state NMR

As the name implies, solution-state NMR requires a liquid sample. In soil research, this typically involves a soil extract such as the important and often studied soil humic and fulvic acid extracts. In solution-state NMR ^1H is the most commonly studied nucleus (since it is the most sensitive nucleus at natural abundance), but there has also been research on ^{13}C , ^{15}N , ^{19}F and other less common nuclei. Soil extracts are typically concentrated via lyophilization and redissolved in a deuterated solvent for solution-state analysis. The use of a deuterated solvent is important for two main reasons: it allows spectrometer locking (which compensates for instrumental drift, leading to more reproducible spectra) and prevents receiver dynamic range issues (i.e., receiver overload) due to the solvent which would otherwise be present in much greater concentrations than the analyte. The choice of solvent is typically dependant on the solubility of the sample. Sodium deuteroxide/deuterium oxide ($\text{NaOD}/\text{D}_2\text{O}$) or deuterated dimethyl sulfoxide ($\text{DMSO}-d_6$) are commonly used solvents in soil analysis, but other solvents such as deuterated methanol or dichloromethane (DCM) can also be employed. Deuterated aqueous solvents are often used to study dissolved organic matter, but have the disadvantage of suppressing signals from exchangeable protons. $\text{DMSO}-d_6$ on the other hand, is a very effective solvent; not only does it help dissolve many compounds that are water insoluble, but it retains exchangeable protons (providing the solvent is dry), and gives sharp line shapes (helping to prevent spectral overlap). However, it is also important to note that $\text{DMSO}-d_6$ will give a signal in ^{13}C spectra, while $\text{NaOD}/\text{D}_2\text{O}$ will not (Simpson et al., 2011). Further, DMSO is an incredible solvent but is only effective when the soil is in the protonated form, which can be achieved by H^+ -ion exchange or by adding acid.

The mass of sample required for NMR analysis depends on the type of NMR probe used. In general, a greater sample mass means that there are more spins to be analyzed, and thus more signal, providing that the sample is not limited by solubility. A standard solution-state probe is 5-mm in diameter with $\sim 600\ \mu\text{L}$ of sample, and is excellent for most applications. Some ~ 50 – $200\ \text{mg}$ of sample are recommended for a 5-mm probe. While the NMR detection limits for individual compounds can be on the order of nanograms (ng), soil is a complex mixture of hundreds of thousands of compounds, and thus much larger masses are required for analysis. Larger probes up to 8 or 10-mm (a few mL) are also available if there is sufficient sample, however, RF homogeneity in larger probes is often reduced and pulse field gradients (required for diffusion, complex 2D NMR and advanced water suppression)

are not always available. On the other hand, if the sample is mass limited (i.e., only a very small mass is available) smaller diameter probes such as 1.7 or 1-mm probes can be used. The benefit is that smaller diameter probes show a greater mass sensitivity (i.e., signal per unit mass). These probes allow analyses of samples in the 1–3 mg range. In general, if sufficient mass is available, the use of a 5-mm probe is recommended and these have been the most commonly used for the study of soil extracts.

Solid-state, HR-MAS and CMP NMR

All of these techniques involve packing a sample into a small rotor, which is then rapidly spun. The sample is spun at the “magic angle” ($\sim 54.74^\circ$) relative to the magnetic field, which helps reduce broadening due to anisotropic interactions in solid and semi-solid components. Despite the spinning, the anisotropic interactions are still strong enough so that solid-state spectra have broader line shape than solution-state spectra. Further, pure solid probes typically do not have a lock channel (leading to potential chemical shift drift) or pulsed field gradient (useful for many 2-D experiments and diffusion-based spectral editing). Pure solid NMR uses dry samples, for example soils that were heated to remove moisture. The sample should be packed as tightly as possible to increase the mass of sample to be analyzed. The size of the rotor determines the maximum sample that can be added, with 4-mm rotors being the most common and holding ~ 100 mg of sample. Larger 7-mm (~ 300 – 400 mg sample mass) rotors are available, but they cannot be spun as fast, leading to potential issues with line broadening and spinning side bands (a form of spectral artefact). For an excellent review on solid-state NMR analysis of natural organic matter (including soil) see the treatise by Mao et al. (2017).

The HR-MAS and CMP NMR methods also employ rotors, but can additionally analyze solution and gel-like samples, allowing the study of interactions between the physical phases. Both techniques typically use a gradient and a lock, allowing for more reproducible and gradient-based experiments. HR-MAS can be used to analyze the solution-state and semi-solid/gel components of a sample. In a “hydrated” soil, this would include any compounds present in the solution-state, and the gel-like, hydrated edges of the soil. Further, the gel-like domains do not exhibit such strong anisotropic interactions compared to the solid-state, leading to line shapes that are better than solid-state (though still not as good as the solution-state). The CMP method takes the benefits of HR-MAS a step further and allows analysis of all phases in the sample resulting in liquid, gel and solid sub-spectra from complex heterogeneous samples. An example of the use of CMP for soil structural elucidation is shown in Fig. 1 (Masoom et al., 2016). Here, three spectra resulting from different components of the swollen soil are present along with assigned peak regions and a 2-D NMR spectrum of the swollen soil shows the additional spectral dispersion and information that can be elucidated through CMP analysis of unaltered soil.

Fig. 1 (A) The 2-D ^1H – ^{13}C Heteronuclear Single Quantum Coherence (HSQC) spectrum (see Table 2) and (B) ^1H spectra of a whole soil recorded using a comprehensive multiphase NMR probe. The numbered boxes in the 2-D spectrum indicate the peak regions corresponding to the resonances as follows: (1) Aliphatic single bonds and amino acid side chains, (2) Alpha proton on amino acids, (3) Methoxy peak from lignin, (4) CH_2 groups from carbohydrates, (5) Anomeric protons from carbohydrates, (6) Aromatic lignin and phenylalanine, (7) Aromatic signals from tyrosine and tryptophan. The three 1-D spectra indicate different components of the soil, separated based on their molecular motion. Adapted with permission from Masoom H, Courtier-Murias D, Farooq H, et al. (2016). Which NMR technique should I use and when?

This is best addressed by a series of queries

1) Is it important to preserve all interactions or the exact structural profile of the sample as close as possible to its natural state?

If the answer is yes, and the material is a solution, then “direct NMR” may be the best approach. Direct NMR is simply the use of advanced water suppression that allows an aqueous based medium to be studied as it is (i.e., without sample preconcentration or alteration) (Lam and Simpson, 2008).

If the answer is yes, but the material is for example a swollen soil, then CMP NMR can be employed to study the solutions, swollen components and solids in the soil in their natural state (Masoom et al., 2016). The HR-MAS technique is also an option if only the swellable components are of interest.

2) Do I just need a compositional overview to compare samples across a series?

If the answer is yes, and the material is a solution, then traditional extraction or preconcentration and then solution-state NMR is recommended. Screening with 2-D NMR greatly increases resolving power, in addition to giving enhanced connectivity information, and is generally encouraged, if sufficient spectrometer time is available.

If the answer is yes, and the material is not a solution, then drying and studying the sample by solid-state ^{13}C NMR is an effective way to compare carbon distribution across samples.

3) Is there anything I should avoid?

Generally, it is not ideal to take a true solution, for example dissolved organic matter, dry it and study it as a solid. For example, consider the example of a solid NMR spectrum collected at 75 MHz ^{13}C (300 MHz ^1H) if an exponential function corresponding to 30 Hz line broadening is applied during processing this leads to a resolving power of ~ 400 –500 peak capacity across the ^{13}C spectral window. However, if the same sample were freeze dried redissolved and a 2-D solution-state NMR spectrum was collected, the resolving power could approach 2,000,000 (Hertkorn et al., 2007) providing a much deeper insight into a dissolved sample. Conversely, if a sample is not in solution in nature, then it is important to balance the potential fractionation and sample alteration that can occur during extraction.

Second, direct NMR and CMP-NMR are not always the “best.” As an example, for direct NMR even on a highly sensitive cryoprobe, it can take >24 h to profile a sample of water with only ~ 2 ppm dissolved organic matter. However, if a litre of the sample was freeze dried and the sample redissolved in 600 μL of solvent, a better SNR would be obtained in minutes. Thus, unless there is an overwhelming reason to study a sample without preconcentration (for example loss of volatiles on freeze drying, or the natural aggregated state being critical) then traditional concentration is recommended. A similar argument can be made for CMP-NMR. Consider, for example, a researcher who wants to see how carbon distribution changes across vegetation-rich horizons. If the plant material is taken as it is (i.e., no drying) it may be $\sim 80\%$ water. Of the remaining 20% perhaps only 40% is a “true” solid. This means that if CMP-NMR is applied, the solid fraction will give only $\sim 8\%$ of the signal compared to drying the entire sample, packing it into a rotor and analyzing it as a pure solid. The resultant information is, of course, different: CMP-NMR would give information on solids as they occur in the true natural state, but if the study aims only to study carbon distribution across different samples, then such information may not be required. As SNR in NMR is proportional to the square root of the number of scans, then in our example, the solid-state NMR of the dried sample could be collected ~ 150 times faster than studying the true solid fraction in the natural state using CMP-NMR.

Ultimately, the type of NMR most ideal for a particular study depends on the research questions being posed. The important point is that modern NMR now offers many new opportunities, techniques and experiments that were not available 20 years ago and it is critical that the next generation of soil researchers embrace all possibilities to propel the field forward efficiently.

Low field NMR, hyphenated NMR and magnetic resonance imaging (MRI)

While the focus of this chapter is mainly on high-field NMR spectroscopy, these three additional techniques can also be useful in the study of soils. Low field NMR refers to the use of much weaker (often permanent) magnets for sample analysis. This of course comes with two major disadvantages: lower resolution and sensitivity compared to high field spectrometers. However, there are also major advantages: low field NMR spectrometers are significantly cheaper, in addition to being portable. This means that, in theory, a low field spectrometer could be taken into the field to perform analyses. Although the lower resolution and sensitivity would pose a challenge, NMR technology is constantly improving and the potential for in-field measurements is increasing. Though standard spectroscopy techniques may be more challenging at low-field, fast field cycling (FFC) and relaxometry techniques are very feasible (Conte and Meo, 2020). The FFC method works by examining the changes in longitudinal relaxation time (T_1) at various field strengths. The strength of this technique lies in the fact that it can explore slow dynamic motions, such as those occurring at the surface of porous media, and that are often missed in high-field relaxometry. For example, soil pore size can be correlated with the relaxation time, helping to understand the underlying water–soil dynamics.

Fig. 2 (A) A chromatogram of a Harvard Forest fulvic acid sample. (B) The structures, NMR spectrum and peak assignments of the compounds corresponding to peak 19 in the chromatogram. (C) A computer predicted NMR spectrum for the compounds identified, used to increase confidence in the structural assignments. Adapted from Simpson AJ, Tseng LH, Simpson MJ, et al. (2004). The application of LC-NMR and LC-SPE-NMR to compositional studies of natural organic matter. *Analyst* 129: 1216–1222 with permission from the Royal Society of Chemistry.

Hyphenated NMR refers to the combination of NMR with additional analytical techniques. For example, liquid chromatography (LC) could be used to help fractionate the sample (decrease spectral overlap), followed by a solid phase extraction (to help concentrate the sample) and then split to NMR and mass spectrometry (MS) for detection. This would give the ultimate set of information about a sample: the NMR spectra could be used to elucidate the structures of the individual compounds that elute in the column and mass spectrometry could help detect compounds whose concentrations are insufficient for NMR. One example of this is a 2004 publication that demonstrated the preliminary use of both LC-NMR and LC-solid-phase extraction (SPE)-NMR to study natural organic matter in both soils and water samples (Simpson et al., 2004). Fig. 2 shows a chromatogram of a soil fulvic acid sample, along with the ^1H NMR spectrum from resulting peak 19.

Based on the ^1H spectrum and comparison to a predicted spectrum, peak 19 was identified to be a mixture of (2E)-3-(4-hydroxy-3-methoxyphenyl)acrylic acid and 1-ethyl-4-methoxybenzene. The study noted that although MS was not employed, it would further improve the ease of compound identification. Though LC-NMR-MS is a very powerful combination of techniques, it requires multiple instruments, and thus expertise in both MS and NMR to set up properly, and due to the complexity of soil, separation may not always be sufficient for unequivocal structural assignment. Nonetheless, hyphenated NMR retains considerable potential for the study of soil organics.

Magnetic resonance imaging utilizes similar principles to NMR, but results in an “image” of the sample as opposed to a spectrum. Commonly applied in the medical field, MRI uses a factor such as relaxation time to differentiate between different components of a sample. This has seen significant use in the study of aggregation and water transport processes in porous media. For example, the study by Pohlmeier et al. examined the change in water content of the soil root interface of a castor bean plant (Pohlmeier et al., 2010). Fig. 3 shows the setup of the plant growth itself, along with a relaxometry-based 3-D difference spectrum, showing the difference in water content after 6 days. It was found that there was a significantly greater change in water content near the upper central part of the soil, whereas the lower region did not have as much uptake. As another example, a water-soluble tracer could be used to see where or how quickly water can pass through a soil, giving an understanding of the soil’s permeability/water retention.

NMR for structural elucidation

A major benefit of NMR is the ability to elucidate unknown structures accurately. To do this, a variety of NMR experiments, outlined in Table 2 can be employed. In brief, by taking advantage of the long- and short-range coupling interactions between nuclei, it becomes possible to elucidate virtually any chemical structure. In fact, NMR is the only technique (except X-ray crystallography, which is limited to crystalline structures) that can solve chemical structures de-novo and without the use of libraries, making it an essential discovery tool.

Fig. 3 (A) Image of a *Ricinus* plant prior to MRI analysis of the soil-root system. (B) The 3-D-MRI Rapid Imaging with Refocused Echoes (RARE) difference spectrum of the soil root system (right). A darker orange color indicates a larger change, and the two long cylinders are marker tubes. Adapted from Pohlmeier A, Vergeldt F, Gerkema E, et al. (2010). MRI in soils: Determination of water content changes due to root water uptake by means of a multi-slice-multi-echo sequence (MSME). *The Open Magnetic Resonance Journal* 3: 69–74.

Table 2 A brief summary of the main NMR experiments of use in structural elucidation in environmental analysis.

Experiment	Information	Interpretation
¹ H NMR 	 An overview of the distribution of ¹H in a sample.	¹ H chemical shift spans ~0–12 ppm. Multiplet patterns can be used to distinguish between neighboring protons through J _{HH} coupling constants. ¹ H in the D position is exchangeable and would not be present in D ₂ O.
¹³ C NMR 	 An overview of the distribution of ¹³C in a sample	Unlike ¹ H NMR, ¹³ C NMR has a much wider chemical shift range of ~250 ppm. Therefore, it exhibits much higher spectral resolution. ¹³ C suffers from lower sensitivity in comparison to ¹ H. ¹ H decoupling is required to remove ¹ J _{CH} couplings.
2-D ¹ H— ¹ H COSY 	 A liquid-state experiment identifying ¹H—¹H correlations between neighboring protons.	Correlation Spectroscopy (COSY) is a 2D NMR technique that shows the connectivity between neighboring protons. In this example, B couples to C so cross peaks are at the corners of a rectangle connecting the 2 protons. As COSY is only between neighbors, proton B does not correlate with proton D.

(Continued)

Table 2 (Continued)

Experiment	Information	Interpretation
2-D ^1H—^1H TOCSY 	 A liquid-state experiment showing long range ^1H—^1H correlations.	Total Correlation Spectroscopy (TOCSY) 2D NMR technique that shows the connectivity of all protons in a spin system. Unlike COSY, TOCSY transfers through an entire ^1H—^1H network. Relays do not pass through quaternary positions so A cannot “see” B. However, B “sees” C and D as there is an unbroken network of ^1H spins connecting them.
2-D ^1H—^1H NOESY/ROESY 	 2D NMR technique that shows connectivity through space rather than bonds, in the liquid-state. Key experiment for conformational analysis.	Nuclear Overhauser Effect Spectroscopy (NOESY) and Rotating-Frame NOE Spectroscopy (ROESY). For small molecules in NOESY dipolar interactions through space are opposite phase to the diagonal and chemical exchange peaks the same phase. For large molecules both spatial interactions and the exchange have the same phase as the diagonal.
2-D ^1H—^{13}C HSQC 	 A liquid-state one bond ^1H—^{13}C correlation experiment.	Heteronuclear Single Quantum Coherence (HSQC) is a 2D NMR technique that correlates ^1H chemical shift and ^{13}C chemical shifts for directly bonded C and H. High spectral dispersion helps reduce overlap in mixtures. NOTE: Carbonyl is absent in an HSQC spectrum since there is no directly attached ^1H
2-D ^1H—^{13}C HMBC 	 A liquid-state long-range ^1H—^{13}C correlation.	Heteronuclear Multiple-Bond Correlation (HMBC) identifies connectivity between ^1H and ^{13}C up to 2 and 3 bonds away. Critical for piecing together molecular structures de-novo. Importantly, this technique is particularly useful as it shows connectivity with quaternary groups such as carbonyl.
^{13}C CP-MAS 	 A solid state NMR experiments that uses the polarization of neighboring protons to enhance ^{13}C sensitivity under MAS.	Cross polarization magic angle spinning (CP-MAS) is a solid-state experiment commonly used for characterizing environmental samples. CP increases sensitivity by up to 4 times and the recycle delay is determined by the ^1H relaxation time rather than ^{13}C making acquisition faster. If absolute quantification is required Direct Polarization (DP)-MAS (i.e., no CP enhancement) is the gold standard. However recent improvements in CP-MAS are also providing more quantitative results.

Table 2 (Continued)

Experiment	Information	Interpretation
2-D ^1H—^{13}C HETCOR 	 A one bond solid state ^1H—^{13}C correlation NMR experiment. (Note: Polarization transfer can occur between neighboring protons and a carbonyl group.)	Heteronuclear Shift Correlation (HETCOR) is a ^1H—^{13}C correlation NMR experiment often used in solid-state NMR. In this case, this is a ^{13}C detect experiment with CP as a transfer step. In solids interactions are via the stronger ^1H—^1H dipolar couplings rather than J-couplings. CP conditions have to be optimized carefully to observe only single bond ^1H—^{13}C correlations. Longer cross polarization times give rise to long range as well as short range correlations.
2-D ^{13}C—^{13}C DARR 	 2D solid-state ^{13}C—^{13}C correlation via dipolar couplings between ^{13}C spins.	Dipolar Assisted Rotational Resonance (DARR) is a solid-state ^{13}C—^{13}C correlation experiment. In this case, the correlations are facilitated via ^1H—^{13}C dipolar couplings under MAS conditions. Such experiments are likely too insensitive at natural abundance but are ideal for following the conversion of ^{13}C labelled biomass in the environment.

Multidimensional NMR

Multidimensional NMR offers much greater spectral dispersion, which enables distinction between peaks that would completely overlap in a 1-D spectrum. While the peak capacity (that is, the number of compounds that can be resolved under perfect conditions) in a 1-D ^1H spectrum is estimated to be a few thousand (and $\sim 30,000$ for ^{13}C), the value for a 2-D HSQC is $\sim 2,000,000$ and can jump to the order of 100,000,000 for 3-D spectra (Hertkorn et al., 2007). As such, multidimensional NMR has an unprecedented ability to help understand the chemical makeup of complex soil mixtures. An example of a spectrum from a commonly applied 2-D experiment (HSQC) of a soil is shown in Fig. 4 (Soucémariadin et al., 2017). It shows the wealth of information that can be gained from the additional dispersion onto two dimensions, as even individual compounds can be identified in certain cases.

It is also noteworthy that although Table 2 focuses mainly on ^1H and ^{13}C interactions, it is possible to utilize these experiments on any coupled nuclei (though sensitivity constraints must be considered). For example, an interesting recent publication studied the transformation of phosphorus in soil through the use of a ^1H — ^{31}P HSQC experiment, which can be found in Fig. 5 (Vestergren et al., 2012). Here, it was possible to differentiate between the various phosphorus species in the hydroxide extract of a Swedish soil. The authors noted that the signals “linked” by lines indicate resonances that were completely unresolvable in the 1-D ^{31}P spectra, showing the enhanced dispersion afforded by multidimensional techniques.

In addition to 2-D techniques, higher dimensional techniques have also been explored. The first application of 3-D NMR was possibly a 2003 study that used total correlation spectroscopy (TOCSY)-HSQC to assigned plant derived structures in soil (Simpson et al., 2003). However, the most impressive to date is arguably a 2015 study that utilized 4-D isotope filtered NMR to identify the substitution patterns of phenolic compounds from the fulvic acid of a peat soil. The 4-D spectrum is in Fig. 6 (Bell et al., 2015). Essentially, each point on the ^{13}C 1-D spectrum shown has an associated cube that further disperses the signal over two ^1H dimensions and another ^{13}C dimension.

Though these techniques provide excellent spectral dispersion, the major drawback compared to 1-D NMR is the length of experiment. To acquire a multidimensional spectrum, a specific delay in the experimental pulse sequence must be incremented. What this means is that the experiment must be repeated under slightly different conditions multiple times. These repetitions are known as increments and the number of increments determines the resolution in the second dimension. As such, it is common to need more than 100 increments to gather good quality 2-D data, leading to an experiment time that is orders of magnitude longer than for 1-D. With higher dimensional spectra this problem is further exacerbated, and many 3+ dimensional spectra, such as the one in Fig. 6 require costly isotopic labelling (i.e., increasing the amounts of ^{13}C or ^{15}N in the sample) to yield results in reasonable time frames. That said, certain techniques, such as non-uniform sampling (NUS) exist, and help decrease the acquisition time for multidimensional experiments in environmental samples (Farooq et al., 2013). Modern NMR processing involves a Fourier transform of the acquired signal, giving the well-known frequency absorption spectrum. However, the Fourier transform requires

Fig. 4 (A) Overall 2-D ^1H - ^{13}C HSQC spectrum of a spruce soil DMSO extract, and (B) selected regions with identified compounds/moieties labelled. Adapted from Soucémariadin LN, Erhagen B, Nilsson MB, et al. (2017). Two dimensional NMR spectroscopy for molecular characterization of soil organic matter: Application to boreal soils and litter. *Organic Geochemistry* 113: 184–195 with permission from Elsevier.

linearly spaced points; more points give better resolution, but also take longer to acquire. With fast relaxing samples, such as of soil, there is much less signal in the later data points and using NUS (with a weighted bias towards earlier data points) enables acquisition with fewer points, allowing for more scans and thus a larger SNR during the same analysis time.

Quantitative NMR

Though the nature of NMR is inherently quantitative, there are some factors that must be considered to obtain reliable quantitative results. The main consideration is that all components for which quantification is desired must be given sufficient time to relax fully (i.e., return to equilibrium after pulsing), and this condition is considered met if the delay between scans is larger than $5 \times T_1$. T_1 is the spin-lattice relaxation time and can be determined from an inversion relaxation NMR experiment. Simpson *et al.* include a

Fig. 5 (A) The ^1H – ^{31}P HSQC spectrum of a typical haplocryod soil. (B) The regions corresponding to different resonances are labelled, and some individual compounds are identified. practical guide that explains how to estimate T_1 quickly for environmental samples (Simpson et al., 2011). At $5 \times T_1$, more than 99% of the magnetization has returned to equilibrium and the sample is ready to be pulsed again. The T_1 time depends on the sample solvent, presence of paramagnetic compounds and the individual chemical environments themselves. For example, aromatic or ketone compounds tend to relax more slowly as they do not have other protons in close proximity to which they can pass their magnetization. Most NMR experiments are not run under fully quantitative conditions. The reason for this is that an improved SNR in the same unit time can typically be achieved by using delay times $< 5 \times T_1$, often as low as $1\text{--}3 \times T_1$. Though the data cannot be directly quantified, if a qualitative spectrum is desired, the higher SNR is clearly advantageous, especially for longer, multidimensional experiments. Further, data resulting from this are still “semi-quantitative” in the sense that integrals from a spectral region, run under identical conditions, can still be used to compare relative amounts across samples (Simpson et al., 2011).

The other major consideration for quantification is the use of an analytical standard. NMR has the major benefit of needing only a single internal standard, which can be any detectable compound. This is especially useful for quantifying compounds with unavailable/expensive standards (Bharti and Roy, 2012). Further, external standards have also been shown to work very well for NMR quantification. In a method known as pulse length–based concentration determination (PULCON), an external standard sample with accurately known concentration can be used to “calibrate” the NMR, and the calibration obtained from that sample can be used for quantification of any other sample. Given an apt choice and proper storage of a primary standard sample, it can be used as a calibration for extended periods of time, recalibrating as necessary (for example, if the probe is changed, or after a duration of time). Within the detection range of NMR, it typically performs very well with regard to the accuracy of quantification, and shows unparalleled reproducibility (Bharti and Roy, 2012).

In the study of soils, it is common to employ cross polarization (CP) experiments for solid-state ^{13}C analysis. Cross polarization works by transferring magnetization from ^1H to ^{13}C via the dipolar interactions that dominate in the solid-state. This has two major benefits: by transferring magnetization from the proton, which has a higher gyromagnetic ratio, there is an up to ~4-fold improvement in SNR, and since the magnetization originates on the proton, the shorter proton relaxation time can be used for the recycle delay, allowing many more scans per unit time. Thus, CP results in both faster and more sensitive ^{13}C spectral acquisition. Similar polarization transfer can be done in solution-state NMR by insensitive nuclei enhancement by polarization transfer (INEPT) or distortionless enhancement by polarization transfer (DEPT). However, the disadvantage of these techniques is that quaternary carbons (i.e., that are not strongly proton coupled) will not be enhanced as much. This means that not only can some aspects of the sample be under or overrepresented, but that typical CP cannot be truly quantitative. Direct polarization (DP) is the gold standard for quantitative solid-state NMR, though recent work has demonstrated marked improvements in the quantitative ability of CP (Mao et al., 2017). In the solution-state, there is an additional consideration: quantitative carbon spectra require inverse gated decoupling (that is, decoupling only during the acquisition), as opposed to decoupling throughout the whole experiment, to prevent the (non-quantitative) Nuclear Overhauser Effect (NOE) enhancement of proton coupled carbons. This is of particular importance as most chemistry departments use NOE enhancement to improve SNR for routine chemical analysis. Thus, if quantitative data are required on soils, researchers should work with the NMR facility personnel to ensure the experiment and acquisition parameters are optimized rather than use a standard template on a “walk-up” system.

Beyond structure—Studying soil interactions via NMR

Studying non-covalent interactions is arguably the most unique ability of NMR. Examining aspects such as the aggregation of humic substances, or contaminant binding to soil are key aspects of soil research. Multiple methods have been developed which allow NMR to study such interactions and will be explored here. Though these mainly originate from protein research, they have since been successfully applied to the study of soils, and have significant potential in this field. It is also important to note that these techniques have been developed for solution-state studies, albeit comprehensive multi-phase and solid-state interactions are considered briefly at the end of this section.

Chemical shift and relaxation changes

One of the simplest methods for studying interactions is to examine changes in chemical shift. By comparing a spectrum of just one compound, with a spectrum of the compound plus its binding partner, a change in chemical shift may indicate binding. Fig. 7 shows an example of the changing chemical shift of 4'-Fluoro-1'-acetophenone, as the concentration of fulvic acid increases (Dixon et al., 1999).

Of note, the chemical shift changes are not very large, and could easily be overlooked because pH and ionic strength changes between samples if enough care is not taken. Although by far the simplest, this is not the most versatile technique, especially since not all binding interactions will result in significant changes in chemical shift.

On the other hand, studying the relaxation time of a compound can be more reliable, though more time-consuming. The relaxation time depends on several factors, but key here is the size and shape of the compound. Macromolecules such as proteins, or humic colloids have restricted molecular motion, leading to much shorter relaxation times compared to small molecules. If a humic colloid interacts with a small molecule, the molecule's motions are restricted and the relaxation time decreases. As such, by examining the relaxation time of the molecule under various humic concentrations (or vice versa), binding can be studied. Table 3, from the same study by Dixon et al., demonstrates the changing relaxation time (Dixon et al., 1999).

The change in relaxation time is much more dramatic than the chemical shift, and can be used to estimate quantitatively the proportion of bound vs free molecules and thus binding coefficients. Though easy to perform, this technique has a few disadvantages: it is time consuming and rarely gives information on where the binding occurs, which are factors that can be addressed by additional NMR techniques.

Diffusion-based techniques

Diffusion-based NMR, namely the 2-D technique known as diffusion ordered spectroscopy (DOSY) can also be used to study interactions. This technique differentiates molecules based both on the chemical shift and the diffusion coefficient. Thus, the basis

Fig. 7 The change in ^{19}F chemical shift of 4'-fluoro-1'-acetonaphthone as the concentration of fulvic acid increases. The fulvic acid concentrations are as follows: (A) 0 mg mL^{-1} , (B) 4.5 mg mL^{-1} , (C) 6.75 mg mL^{-1} , (D) 9 mg mL^{-1} , (E) 13.5 mg mL^{-1} . of the technique is similar to that of the relaxation measurements: small molecules have fast diffusion rates, and when bound to a macromolecule (or aggregate) the diffusion rates slow down significantly. A benefit of DOSY over relaxation measurements is that it is quite feasible to study multiple small molecules at the same time. This results in much faster throughput, and similar information regarding binding coefficients can be extracted, in addition to molecular weight information. As an example, Šmejkalová and Piccolo utilized DOSY to study the aggregation and disaggregation of soil humic substances, and a humic acid DOSY spectrum, as well as 1-D ^1H slices are shown in Fig. 8 (Šmejkalová and Piccolo, 2008). Here, the resonances near the top represent the more slowly diffusing (that is, larger) components. In this study, increasing humic concentrations were correlated with larger molecular sizes, supporting the fact that humic samples were aggregating into supramolecular associations. Though DOSY can provide higher throughput than relaxation measurements, it is slightly more difficult to set up, and provides rather little information on the binding orientation.

Nuclear overhauser effect-based techniques

Nuclear Overhauser effect spectroscopy (NOESY) has long been a gold standard for examining interactions in proteins, and can be useful in studying soils. NOESY and the closely related technique known as rotational nuclear Overhauser effect spectroscopy (ROESY) both rely on dipolar coupling interactions. What this means is that these techniques can look at interactions through physical space, as opposed to coupling through bonds employed by techniques such as HSQC. This is very powerful as it can help to elucidate the exact binding conformations of compounds with soil humic substances. NOESY and ROESY can be used in combination to distinguish between exchangeable protons (OH or NH groups) and other interactions. If a small compound binds to a large macromolecule, a cross peak will appear in the NOESY spectrum, which can identify precisely where binding occurs. Further, NOESY can help elucidate the 3-D structures of large molecular assemblies, by analyzing whether or not certain sites are in

Fig. 8 (A) The ^1H DOSY spectrum of humic acid extracted from a Brazilian hydromorphic soil. (B) The 1D— ^1H spectral “slices” through the diffusion axis of the DOSY spectrum. Aggregation and disaggregation of humic supramolecular assemblies by NMR diffusion ordered spectroscopy (DOSY-NMR). *Environmental Science and Technology* 42: 699–706. Copyright 2008 American Chemical Society.

close spatial proximity. Although the information gained from NOESY is quite powerful and the experiment is fairly easy to setup, NOESY can suffer from significant overlap and tends to have lower sensitivity than saturation transfer techniques, which are discussed next.

Saturation transfer difference (STD) techniques

The STD techniques are the most complex, (and arguably the most powerful) interaction studying techniques, and were specifically developed for this purpose. The STD technique operates by saturating (irradiating with radiofrequency energy) the peaks that are specific to a macromolecule (or set of macromolecules) and examining the changes in intensity of the NMR spectrum of the small molecule (ligand). If the ligand is sufficiently close to the macromolecule ($\sim 4\text{--}6\text{ \AA}$), it will acquire some of the saturation of the macromolecule, resulting in a decreased NMR signal intensity. The major benefit of this technique is that, since the STD effect is sensitive to the distance from the macromolecule, NMR signals from areas of the compound that do not bind are not attenuated. By gathering a series of spectra and subtracting them as seen in the Fig. 9, contributions from the nonbinding components are eliminated. This is known as saturation transfer double difference (STDD) and helps create flat baselines that allow changes from binding to be quantified accurately. The result is that STD NMR can be used to create an “epitope map”—a representation of the exact areas on the ligand that bind the macromolecule. An example of an epitope map in Fig. 10 (Shirzadi et al., 2008) shows the molecular level mechanistic information obtained through STD. Overall, STD NMR gives excellent mechanistic binding information, but though more sensitive than NOESY, may still require relatively long experiment times.

Reverse Heteronuclear Saturation Transfer Difference (RH-STD), utilizes similar principles to STD, but relies on saturating the ligand, as opposed to the macromolecule. This can help to determine which specific macromolecular components bind to the ligand. For example, a study of soil interactions with perfluorinated contaminants found that perfluorooctanoic acid had a great preference for the protein derived domains in a soil (Longstaffe et al., 2010). A significant drawback of RH-STD is that the ligand must be saturated without saturating the macromolecules. This typically requires a heteronucleus, the most common of which is ^{19}F , and is thus limited to samples that contain such a nucleus. Nonetheless, this is a powerful technique and since ^2H can be incorporated into nearly any organic molecule without changing its chemistry, it holds great potential for future interaction studies.

Studying interactions via CMP NMR

Though the previously discussed techniques are mainly used in the solution-state, CMP NMR can study interactions between phases, which is crucially important to the understanding of contaminant mobility and sequestration. An example of soil CMP analysis is shown in Fig. 11 (Masoom et al., 2015). Here, the molecular journeys of perfluorooctanoic acid (PFOA) and perfluorophenol (PFP) through the various phases of the soil were examined using ^{19}F CMP NMR. There are two things to note in the NMR spectra of this figure: the line shapes become significantly broader going from the solution to solid-state and PFP and PFOA have very different sequestration behaviors, with the majority of PFOA remaining in the solution-state, while most PFP enters the gel/solid-state. The right side of the figure shows a kinetic curve of the fate of the fluorinated contaminants, showing that NMR can be used to obtain time resolved interaction data. Overall, CMP NMR, as well as HR-MAS have excellent potential for the study of soil contaminant interactions.

Fig. 9 An illustration of the process involved in generating an STD epitope map. First, two reference spectra (A) which has both the ligand and humic acids and (B) which contains only the humic acids are gathered. Spectrum (C) is the double difference reference spectrum and is generated by subtracting (B) from (A). Following this, the STD spectra (D) (humic acid and ligand) and (E) (only humic acid) are gathered and subtracted to make spectrum (F), the STDD spectrum. By comparing spectra (F) and (C), an epitope map can be created as shown in Fig. 10. Reproduced with permission from Shirzadi A, Simpson MJ, Xu Y, Simpson AJ. (2008). Application of saturation transfer double difference NMR to elucidate the mechanistic interactions of pesticides with humic acid. *Environmental Science and Technology* 42: 1084–1090. Copyright 2008 American Chemical Society.

Studying interactions via solid-state NMR

To close this section, we briefly consider the work by Sachleben et al. which is an example of studying interactions in the solid-state (Sachleben et al., 2004). Here, the interactions of a hydrophobic pollutant (pyrene), with plant derived cuticular matter (which contributes aliphatic compounds to soil organic matter) was examined through the use of both one-dimensional and multi-dimensional solid-state NMR. Based on analyses of the relaxation time and chemical shift anisotropy of pyrene, it was found that pyrene shows anisotropic motion under sorption to cutan, whereas under sorption to cutin the motion is initially isotropic but become anisotropic after 22 months. The study noted that this type of work provides an improved understanding of pollutant sorption to soil organic matter, which can help develop improved sorption models and soil remediation techniques.

Fig. 10 A comparison of the (A) double difference reference and (B) STDD spectra of diflufenzopyr and humic acid (left). The resultant epitope map (C) shows the degree of interaction of the moieties of the molecule with humic acids, the largest of which is the proton labelled e. Sensitivity improvements in NMR

It is without doubt that the greatest weakness of NMR is its relatively low sensitivity, and therefore there has been substantial effort spent improving NMR sensitivity. As was alluded to in the introduction, the greater the difference in energy between the two spin states, the larger the net magnetization produced, which gives rise to a larger detectable signal. Two major factors that affect this energy difference are the strength of the magnetic field and the gyromagnetic ratio of the nucleus of study. The gyromagnetic ratio is fixed by the nucleus of study (see the section on choosing a nucleus for more information), while the strength of the magnetic field

depends on the NMR spectrometer available. Modern NMR spectrometers typically use very strong superconducting magnets that require cooling by liquid helium and nitrogen. The field strengths of modern high-field NMR spectrometers vary widely from <300 MHz to ~1.2 GHz, though spectrometers in the upper range are more rare; they are considerably more expensive both to purchase and in access fees. In the field of NMR, the field strength is commonly denoted in MHz (as opposed to the SI unit of Tesla), which is the resonant frequency of ^1H at that field strength. Higher field strength brings two major advantages: increased spectral resolution, which scales proportionally with the magnetic field, and increased SNR, which typically scales with the field to the power of $3/2$ (Webb, 2012). Overall, stronger magnets typically give much improved spectra and given just the improvements in NMR field strength, experiments that were not possible on spectrometers from the 1990s are now much more feasible.

Another commonly touted example of sensitivity improvement in NMR are cryoprobes. In this case, by cryogenically cooling the electronic components involved in the NMR circuitry, the amount of thermal noise (the main source of noise in NMR) can be reduced, resulting in up to 3–4-fold SNR improvements (Styles et al., 1984). However, cryoprobes are typically not as effective for samples with high salt contents, and thus the benefit for soil analysis is quite variable and unlikely to reach 3–4-fold improvement (Simpson et al., 2011). That said, probes with varying detection coil architectures can still provide sensitivity (and other) improvements. For example, an inverse probe, in which the proton coil is closer to the sample, will result in better ^1H spectra, while a broadband probe (optimized for the heteronucleus) will give better ^{13}C spectra by a factor of ~2 (Simpson et al., 2011).

Conclusion

Nuclear Magnetic Resonance is a powerful analytical tool for the study of soil constituents and interactions. Despite the large offering of NMR experiments, many of which can yield excellent information and insights, the vast majority of soil NMR is currently restricted to solid-state ^{13}C NMR, in large part due to the historical use of solid-state NMR in early soil research in the 1960s–1990s. However, it is critical for researchers to explore all branches of NMR and the authors intend this article to be a small step towards making the various types of NMR more accessible in soil research. For example, saturation transfer difference techniques have great potential to help understand the critically important processes of aggregation, sequestration and other non-covalent interactions that are extremely difficult to study by MS, but only a few studies involving these techniques have been published. The HR-MAS and CMP NMR techniques open the door to the analysis of soils in their natural state, giving information about multi-phase processes that occur in the real world. With there being an increasing shift from questions such as “What are humic substances?” to “How does the soil aggregate structure form” or “Why does herbicide X bind more than herbicide Y to a soil,” it will become more and more important to study soils in their natural, hydrated state. Thus, preparations that involve drying to generate “pure” solids or extractions to generate “humic” fractions are no longer the only ways forward for soil research.

MRI is still the most effective approach to look at human anatomy and NMR is a close cousin with the ability to look inside intact soils with bond-level specificity. In many scenarios, especially those concerning novel structures and non-covalent interactions, NMR is unique in its abilities among other modern instrumentation. As such, it holds the key to answer some of the most challenging and complex questions facing the field. It is equally important that the next generation of soil researchers fully embrace cutting edge NMR technologies, and that current and future NMR experts (and manufacturers) strive to make NMR research more accessible to those from “non-traditional” disciplines such as soil and environmental science. In summary, NMR has a critical and central role to play in the arsenal of analytical technologies required to understand the role of anthropogenic impacts on the environment and their subsequent effects on ecosystems and human health.

Abstract

This chapter is devoted to the application of neutron-gamma methods, mainly pulsed fast thermal neutron analysis (PFTNA), for soil elemental measurement and mapping. Herein, we provide a description of general PFTNA principles, main components and configurations of a PFTNA field system, and procedures for primary data (gamma spectra) acquisition for determining soil elemental content. In addition, methodology of field PFTNA measurements and the creation of soil elemental maps will be discussed. Soil elemental maps plotted from PFTNA measurements are useful in soil science and for assessing modern agricultural practices. Results of PFTNA can provide soil carbon content in the 30-cm depth soil layer and such information can be useful for carbon credit estimates.

Key points

- Description of general principles of neutron-gamma analysis, modifications of neutron-gamma analysis, measurement system components and their configuration for field applications are provided.
- Assessing soil elemental content from pulsed fast/thermal neutron analysis results, soil element datasets required for mapping and mapping procedures are discussed.
- Examples of agricultural field elemental distribution maps and data on total field soil carbon content suitable for carbon credit estimates relevant to the climate change debate are presented.

Introduction

Soil science plays an importance role in optimizing food production including the understanding of environmental processes such as soil carbon sequestration and soil health. State-of-the-art soil science and agricultural practices for increasing soil productivity and profitability require precise knowledge of the chemical composition of large volumes (tens, hundreds, thousands of cubic meters) of soil, composts, and fertilizers. Traditional chemical analysis is labor intensive and time consuming since they require a large number of samples to be collected for laboratory processing. To date, various physical methods for soil element determination (mainly carbon, C) have been developed, which include *in situ* determinations of some soil elements. Among these, different modifications of neutron-gamma analysis [Wielopolski \(2011\)](#) are a more promising alternative to traditional chemical analysis procedures. The neutron-stimulated gamma analysis method can be used for *in situ* measurements of primary elements in agricultural soils (e.g., C, Si, O, H, Fe, and K, see [Table 1](#) for element names), C:N ratio of composts ([Yakubova et al., 2019](#)), and

Cl (chlorine) contamination of soils. This method is a non-destructive analysis that requires no sample preparation and can perform multi-elemental analyses of large volumes that are negligibly affected by local sharp changes in elemental content.

Neutron-gamma analysis is based on detecting gamma lines that appear due to neutron nuclei interactions. Many nuclei can be detected and quantified by the presence of these characteristic gamma lines. State-of-the-art nuclear physics methodologies and instrumentation combined with commercial availability of portable pulse neutron generators, high-efficiency gamma detectors, reliable electronics, and measurement and data processing software have currently made the application of neutron-gamma analysis possible for routine measurements in various fields of study. These are the detection of hazardous materials (explosives, drugs, and dangerous chemicals), diamond detection, planetary science applications for obtaining information on bulk elemental composition, archaeological site surveying and provenance studies, elemental composition of human and animal bodies, real-time elemental analysis of bulk coal on conveyor belts, chloride content of reinforced concrete, and in oil well logging [Valkovic \(2016\)](#). Neutron-stimulated gamma ray analysis can also be used in soil science for in situ measurements of soil carbon and other soil elements. Soil carbon measurement is based on detecting 4.44 MeV gamma rays issued from carbon nuclei excited by fast neutrons promptly after the interaction ([Wielopolski, 2011](#)). Note that accurate quantification of soil carbon is important since it is an indicator of soil quality that can affect soil carbon sequestration, fertility, erosion, and greenhouse gas fluxes ([Smith et al., 2012](#)).

The general principles of neutron-gamma analysis, modifications of neutron-gamma analysis applicable to soil science, measurement system components and its configuration for field application, neutron-gamma methodology for determination of soil elements, and examples of an application of this method in agricultural settings will be described in this chapter.

General principles of neutron-gamma analysis

Neutron-gamma analysis is based on the registration of gamma rays issued by nuclei upon interaction with neutrons due to different neutron-nuclei interaction processes. Fast neutrons can penetrate a surveyed volume of soil, impact and excite nuclei, and scatter. Neutrons lose some energy (moderating process) due to this inelastic scattering while excited nuclei relax into a ground state issuing gamma rays. For example, the inelastic scattering of fast neutrons on ^{12}C nuclei elevate them to the 4.44 MeV excited energy state ([NNDC, 2013](#)). Excited $^{12}\text{C}^*$ promptly returns to the ground state issuing the 4.44 MeV gamma ray. Finally, the neutron is moderated until thermal energy can be captured by some nuclei. Nuclei issue gamma rays promptly after interaction due to both inelastic neutron scattering (INS) and thermal neutron capture (TNC). In addition, in some cases the interaction of neutrons (both fast and thermal) can lead to the creation of new radioactive isotopes due to nuclear reaction type of (n (neutron), p (proton)), (n, α), (n, t (tritium)), etc. Decay of these isotopes is accompanied by delay activation (DA) gamma rays. Each kind of nucleus and process produces gamma-rays of particular energy. This characteristic gamma line of particular energy can serve as an analytical line for elemental determinations. The list of main soil elements, their characteristic gamma lines, particular energy and processes responsible for line appearance are shown in Table 1. As can be seen, many gamma ray energy lines of interest are in the 1–12 MeV range. The cross-sections of neutron (both fast, 14 MeV, and thermal) interactions with nuclei are shown in [Table 1](#).

The net peak area of an element of interest can be defined from measuring the gamma spectral response. However, for determining the content (or concentration) for the element of interest in soil, the calibration dependence that associates the content of this element with a gamma response peak value is required. This calibration dependence can be created from measurements of gamma spectra of neutron irradiation of reference soils with well-known elemental contents. The elemental content of reference soil can be determined by chemical analysis, or these soils can be prepared by mixing known amounts of substances (e.g., sand and carbon grains).

Modifications of neutron-gamma analysis

Pulsed fast/thermal neutron analysis (PFTNA)

The main difficulty in conducting soil neutron-gamma analysis and determining net peak values of interest (e.g., soil carbon peak) is the overlapping of different gamma lines from nuclei of soil and construction components of the measurement system. Thus, it can be problematic to extract net peaks of interest from the gamma response spectra due to soil irradiation. However, it is possible to separate the gamma ray spectrum due to INS reactions from the total complicated gamma ray spectrum caused by all nuclear reactions using a pulsed neutron generator and certain measurement techniques. By these means, 14.1 MeV neutron flux pulses (with 5–20 μs width and 5–20 kHz frequency) can be used to irradiate studied objects. The INS reactions will only occur during the neutron pulse (5–20 μs range), while TNC and DA processes occur during and between neutron pulses due to relationships between time of neutron moderation, lifetime of thermal neutrons, and lifetime of excited nuclei. The data acquisition system can collect data during neutron pulses at one memory address and switch to another memory address between pulses. The average intensity of TNC spectra under these measurement conditions have practically the same value between pulses and during pulses ([Kavetskiy et al., 2017](#)). Thus, the INS spectrum can be restored by extracting the (TNC + DA) spectrum count rate (measured between pulses) from the (INS + TNC + DA) spectrum measured during pulses.

The measured spectra consist of two parts: spectra of the studied object and spectra of the measurement system (system background spectra). The last spectra can be determined by conducting PFTNA measurements by moving the measurement system away from the ground, floor, walls of buildings, and other large nearby objects. This can be accomplished by lifting the system

above the ground. The (INS + TNC + DA) and (TNC + DA) gamma spectra do not change at heights greater than 3–4 m, and readings in this range can be equated to measurement of the system background. With this background information, the net (INS + TNC + DA) and (TNC + DA) spectra of the object studied can be determined by subtracting the system background spectra from the corresponding measured spectra of the object (e.g., soil). The net spectra will represent the spectra of gamma rays for only the soil (sample) due to INS or TNC + DA processes. After this determination, the net INS spectrum of soil can be restored by extracting the (TNC + DA) soil spectrum from the (INS + TNC + DA) soil spectrum.

Peak values from these spectra can be attributed to nuclei present only in the soil and can be used to calculate elemental content. Carbon, silicon, oxygen, and aluminum concentrations in soil can be determined from the net INS spectrum, while the hydrogen, iron, and silicon can be determined from the net (TNC + DA) spectrum.

Following the classification of neutron-gamma analysis methods given in (Barzilov et al., 2012), the method of neutron-gamma analysis described can be called Pulsed Fast/Thermal Neutron Analysis (PFTNA). This method is currently used for soil element mapping of agricultural fields and has potential use for determinations of total field soil carbon for carbon credit markets.

Tagged neutron method (or associated particle imaging, API, method)

There is another possible means of using neutron-gamma technology for soil elemental analysis. Neutron generators that produce neutrons due to (d (deuterium), t) nuclear reactions are widely used in other gamma-neutron measurement systems (see further). At the (d, t) reaction, both neutrons and alpha particles are generated at the same time, but move in opposite directions. The alpha detector and sample are installed on opposite sides of the neutron generator target. The alpha particle pulse (in the alpha detector) can be used to 'tag' the neutron, and only the gamma rays stimulated by this 'tagged' neutron will be registered. The tagged neutron method is based on measurements of gamma spectra in the alpha-gamma coincidence mode. Several nanoseconds are required for neutrons to reach the sample before gamma rays are produced and registered. The geometry of the alpha-detector setup defines the measurement cone, and only gamma rays (due to INS processes only) from neutron-sample interactions (in this cone) that coincide with alpha particles are acquired.

The gamma spectra measured by the tagged neutron method has two main advantages. First, it produces practically clean INS spectra that are suitable for INS active soil element (C, Si, O) measurements. Second, this gamma spectrum relates primarily to the object studied.

Developing the tagged neutron method for soil elemental analysis is now in progress. Laboratory experiments demonstrated (Kavetskiy et al., 2019) that the carbon minimal detectible level (MDL) in sand-carbon mixtures for the tagged neutron method is better than other neutron gamma methods, in particular PFTNA. Thus, the API method of soil elemental analysis appears to be a very promising direction for the development of a field mobile system with improved metrological parameters.

Measurement system components and their configuration for field application

The configuration of a measurement system for neutron-gamma analysis consists of a neutron source, gamma detector, shielding and construction materials, operational electronics, and data acquisition software. Below we briefly consider the main features of these components.

Neutron sources

Portable neutron generators are primarily used in neutron-gamma analysis systems for field applications. From a radiation safety point of view, use of a neutron generator is preferred because no radiation is produced when the generator is turned 'off'.

Neutrons are produced in the portable neutron generator by (d, t) or (d, d) nuclear reactions when the target is hit (saturated by tritium or deuterium) by accelerated deuterons. Generators can work in continuous and pulsed modes. Generators for applications of the tagged neutron (or API) system have a built-in alpha detector.

Gamma detectors

Among the different types of gamma detectors, scintillation detectors with inorganic scintillators of large volumes (more than 1 dm³, preferably 5–10 dm³) are more suitable for neutron-gamma analysis systems as noted by Valkovic (2016). They have a high Z value and effectively detect a relatively low flux of characteristic gamma rays with energies up to ~12 MeV and provide an energy resolution that enables peaks of interest to be resolved. The interaction of neutrons with nuclei in the material of these detectors does not produce gamma rays that overlap useful signals emitted from samples. Detector materials are void of isotopes that are anticipated in samples analyzed and neutron activation of isotopes inside the detector volume is minimal. Shifts in detector sensitivity due to changing environmental conditions (temperature, etc.) is minimal. Thus, these detectors are suited for field applications of neutron-gamma analysis. Detectors based on sodium iodide NaI(Tl), bismuth germanate Bi₄Ge₃O₁₂ (BGO), and lanthanum bromide LaBr₃(Ce) inorganic scintillators are commonly used in neutron-gamma analysis systems.

Shielding and construction materials

Direct fast neutron flux on the gamma detector and gamma radiation that appear from neutron interactions with detector nuclei produce a large gamma spectral background signal. Large background signals affect minimal detection limits of the measurement system, thereby increasing measurement errors. Shielding used between the neutron generator and gamma detector can help to eliminate this problem in the measurement system. Fast neutron shielding consists of two or three components that slow down fast neutrons to thermal energy (moderator), absorbs thermal neutrons (absorber), and then attenuates the gamma rays produced by different neutrons-nuclei interactions in the moderator and absorber (attenuator). Light materials like water, heavy water, and polyethylene are usually used as neutron moderators, and boric acid is a possible absorber. Lead, tungsten, and iron are usually used for attenuation of gamma radiation. The shielding should be of reasonable thickness and should not produce gamma lines within the energy range of interest.

Construction materials should have minimal susceptibility to neutron activation by fast or thermal neutrons, issue few gamma rays in the energy range of interest, and have minimum high energy gamma rays that increase the system background spectrum. Duralumin can be recommended as construction material for neutron-gamma analysis systems.

Operational electronics and data acquisition software

Operational electronics and data acquisition software used in neutron stimulated gamma analysis systems can be built on the basis of standard electronic blocks paired with a pulsed neutron generator or can be custom-made electronic schemes and data acquisition software. Electronics of the PFTNA system should be capable of acquiring gamma spectra during and between neutron generator pulses separately (split electronics). Electronic boards and ProSpect-Vega software from XIA LLC (Hayward, CA) demonstrated reliable workability in PFTNA systems (Yakubova et al., 2014). The data acquisition system for API equipment should work in the alpha-gamma coincidence mode. This can be built using standard electronic blocks produced by Ortec or Canberra companies.

The PFTNA field mobile system configuration

The field mobile system should be mounted on a mobile platform and as previously mentioned, consists of a neutron generator, gamma detector, shielding, operational electronics, and data acquisition software. This system can be towed by tractors or all-terrain vehicles over various field terrains. This system should have an autonomous power system that provides an uninterrupted power supply for at least one working day.

The following is one example of the system used to conduct research at the USDA-ARS National Soil Dynamic Laboratory in Auburn, AL. This system works in the PFTNA mode and has three separate construction blocks (Fig. 1). Components of the first block are an MP320 pulsed neutron generator (Thermo Fisher Scientific, Colorado Springs, CO), an R2D-410 neutron detector (Bridgeport Instruments, LLC, Austin, TX), and a power system (Fig. 1A). The neutron generator has a neutron pulsed output of

Fig. 1 Overview of the PFTNA system: (A) neutron generator, neutron detector, and power system; (B) three NaI (Tl) detectors; (C) equipment operation; (D) general view of a showing individual components. Modified from: Kavetskiy A, Yakubova G, Torbert HA and Prior SA (2017) Neutron-stimulated gamma ray analysis of soil. In: Maghraby AM (ed.) *New Insights on Gamma Rays*, pp. 133–178. INTECH: <https://www.intechopen.com/books>.

10^7 – 10^8 n s⁻¹ (depending on parameter settings) and a neutron energy of 14.1 MeV. Components of the autonomous power system are four DC105–12 batteries (12 V, 105 Ah) and a DC-AC inverter (CGL 600 W series; Nova Electric, Bergenfield, NJ). This inverter transformed 12 VDC battery power to 110 VAC. A Quad Pro Charger model PS4 (PRO Charging Systems, LLC, LaVergne, TN) is used for charging batteries during nighttime garage storage of the system. The first block also contains water, iron, and boric acid shielding for isolating the detectors from the neutron beam and focusing the beam on the soil area of interest. The second block has the gamma ray measuring equipment (Fig. 1B) and contain three 12.7 cm × 12.7 cm × 15.2 cm scintillation NaI(Tl) detectors (Scionix USA, Orlando, FL). A Cockcroft–Walton type high voltage power supply (C1248 series Hamamatsu Photonics K.K.) ensures high output linearity of the gamma detectors photomultiplier tubes (PMT) while maintaining low power consumption by detectors. Electronic boards (XIA LLC, Hayward, CA) connected to the PMT included fixed analog gain, 14-bit resolution and 100 MHz sampling rate analog-to-digital converter, and a 2048-channel multichannel analyzer (for each detector) to acquire and transfer gamma spectra to the operational computer. A GPS system (Trimble R2 receiver, Trimble Inc.) with an accuracy of ±0.5 m connected to the operational computer by Bluetooth technology identifies and records the geographical position of the acquired gamma spectra. For equipment operation, the third block (Fig. 1C) housed a laptop computer for controlling the neutron generator, detectors, and data acquisition system (ProSpect 0.1; XIA LLC) (Fig. 1C).

The dimensions of this mobile system are 75 cm × 23 cm × 95 cm and weighs ~300 kg. While the frame's primary construction material is aluminum, the shielding (mainly iron) contributes more weight. This system can be towed over the field at speeds up to 10 km h⁻¹ during measurements in the scanning mode. An Android tablet (Samsung Galaxy Tab S5e) utilizing Google Maps [Google \(2019\)](#) and specially developed software is connected by Bluetooth technology to the GPS. The tablet is in the towing vehicle (within the driver's view) to provide operational information. Information provided on the tablet includes the current system position, traversed path, total spectra acquisition time, etc., and the driver utilizes this information for selecting pathways for scanning field measurements.

Results of PFTNA measurements and soil elemental content

Raw data

Two gamma spectra are acquired from PFTNA measurements: (INS + TNC + DA) spectra acquired during the neutron pulse and (TNC + DA) spectra acquired between neutron pulses. The PFTNA system being towed across the field is shown in Fig. 2. An example of raw (INS + TNC + DA) and (TNC + DA) gamma spectra of soil measured by the PFTNA system described above is shown in Fig. 3.

The net (INS + TNC + DA) and (TNC + DA) spectra of soil can be found by subtracting the system background spectra from the corresponding measured spectra. The net INS spectrum can be restored by extracting the net (TNC + DA) spectrum in count rate unit from the (INS + TNC + DA) spectrum of soil. Net INS spectral peaks with centroids of 1.78 MeV and 6.13 MeV can be directly attributed to silicon-28 (²⁸Si) and oxygen-16 (¹⁶O) nuclei in soil, respectively; the peak with a centroid of 4.44 MeV is complex, but peak area attributed to the carbon-12 (¹²C) nuclei can be determined from this peak. Peaks with centroids at 2.22 MeV and 7.63 MeV in the net (TNC + DA) spectrum of soil can be attributed to hydrogen and iron-56 (⁵⁶Fe) nuclei, respectively.

Fig. 2 The PFTNA system towed over the field.

Fig. 3 Raw (INS + TNC + DA) and (TNC + DA) gamma spectra of soil, system background spectra, and soil net INS and (TNC + DA) spectra.

System background spectra

The system background spectra are acquired when the PFTNA system is raised above the ground (and away from buildings and large objects) by use of a crane (Fig. 4). Measured (INS + TNC + DA) spectra and (TNC + DA) spectra of the PFTNA system at different heights above the ground are shown in Fig. 5.

Relations between different peak areas with height are shown in Fig. 6. The data represented demonstrate that spectra measured at heights greater than 3–4 m can be taken as the system background spectra (see Fig. 3) and can be used in calculations of net INS and (TNC + DA) spectra of soil.

Peak area determinations

After determining the net INS and net (TNC + DA) spectra of soil, areas of corresponding soil element peaks can be determined. Considering that peaks have a Gaussian shape, approximation of peak regions by Gaussian(s) on linear (or non-linear) backgrounds can be done. Peak area is defined as a Gaussian area. Approximation can be done using available software such as IGOR (WaveMetrics, 2018). The Gaussian approximation method is preferable since it can be used for area determinations of non-resolved neighboring peaks, and accuracy of this method of peak area determination is better than the traditional trapezoidal method (Gilmore, 2008).

Examples of peak approximations by Gaussian functions are shown in Fig. 7. The 4.45 MeV peak in the spectra of different sand-carbon mixtures can be approximated by summation of two Gaussian functions with centroids at 4.44 MeV and 4.50 MeV on a linear background. These spectra show that the peak in the sand spectrum can be approximated by one Gaussian function, while two Gaussian functions are needed for good fitting in sand-carbon mixtures. The peak with a centroid at 4.50 MeV can be attributed to the silicon cascade transition peak, while the peak with a centroid at 4.44 MeV can be attributed to carbon. The silicon transition peak varies slightly from spectrum to spectrum, while the carbon peak increases with increasing carbon content in the sample. The value of the carbon peak area can be used for carbon content determinations.

Calibration dependencies

To assess soil elemental content from the net peak area of interest, calibration dependencies should be created. To accomplish this task, PFTNA measurements of field or synthetic soil with well-known elemental contents of interest should be conducted. The following is a discussion of creating the calibration dependence for carbon.

Fig. 4 The PFTNA system is lifted by the crane for measuring background spectra.

Fig. 5 Measured (INS + TNC + DA) and (TNC + DA) spectra of the PFTNA system at different heights above the ground.

Fig. 6 Relations between different peak areas with height.

Fig. 7 Fragments of net INS spectra of sand-carbon mixtures (solid gray line) measured by the PFTNA system described and their approximation in the region of interest (ROI, solid black line around 4.44 MeV) by summing of two Gaussian functions (dashed lines) on the linear background (dashed line, long strokes). (A) sand + 10 w% of carbon; (B) sand + 5 w% of carbon; (C) sand + 2.5 w% of carbon; (D) sand. Modified from: Yakubova G, Kavetskiy A, Prior SA and Torbert HA (2017a) Applying Monte-Carlo simulations to optimize an inelastic neutron scattering system for soil carbon analysis. *Applied Radiation and Isotopes* **128**, 237–248.

Fig. 8 View of calibration pit with sand and pit with 10 w% sand-carbon mixture. Modified from: Yakubova G, Kavetskiy A, Prior SA and Torbert HA (2017b) Measurements of soil carbon by neutron-gamma analysis in static and scanning modes. *Journal of Visualized Experiments* **126**: e56270.

Carbon calibration dependency

Four calibration pits with carbon-sand mixtures of known carbon content were prepared. The size of each pit was $1.5 \text{ m} \times 1.5 \text{ m} \times 0.6 \text{ m}$, and these pits can be seen in Fig. 8. The PFTNA system was positioned over each pit in such a manner that the neutron source was located over the geometric center of each pit. Net INS spectra were calculated for each pit while accounting for the system background spectra as described above. Fragments of peaks around 4.45 MeV in the experimental net INS spectra and their Gaussian approximations are shown in Fig. 7A–D.

It is important to note that peak fitting by summation of two Gaussian functions gives approximately the same value for different component parameters; for this reason, the sum was used in the analysis while areas of the components were not. The silicon cascade transition component in the 4.45 MeV peak was defined as follows. The silicon net peak area in the net INS spectrum of the i -th pit was denoted as SSi_i (centroid at 1.78 MeV) while the 4.45 MeV net peak area in the spectra of i -th pit was denoted as SC_i . Both peak areas in each spectrum were found by Gaussian approximation. The net carbon peak area (centroid at 4.44 MeV) in the i -th spectrum was denoted as $Ccorr_i$, and the carbon content in the i -th mixture was denoted as $Cont_i$. The assumption was that:

$$Ccorr_i = SC_i - f \cdot SSi_i \quad (1)$$

where f is the ^{28}Si nucleus cascade transition coefficient. These designations are shown in Fig. 7 A–D for clarity. $Ccorr_i$ was considered to be directly proportional to the carbon content of the mixture as $s \cdot Cont_i$. Coefficient s gives an idea of the sensitivity to system carbon (cps per unit of the amount of carbon in the sample). Using SC_i and SSi_i data, the values of f and s can be determined by minimizing the following expression:

$$\sum_i (SC_i - f \cdot SSi_i - s \cdot Cont_i)^2 \rightarrow \min \quad (2)$$

The f and s values were found by equating the derivatives of this sum with respect to f and s set to zero. The standard mathematical software MathCAD was used for these calculations. The defined value of f (0.056) for the example discussed was very close to the theoretically calculated value of the cascade transition coefficient for silicon (0.0547; Herman et al., 2007). This agreement supports the use of this method for determining carbon calibration dependence.

The dependence of the net carbon peak area ($Ccorr_i$) with pit carbon contents ($Cont_i$, expressed in weight percent) is shown in Fig. 9. As can be seen, this is a directly proportional dependence that passes through the 'zero-zero' point (in frames of accuracy of $Ccorr_i$ determinations). The slope of this dependence is the coefficient s (defined as equal to $13.5 \pm 0.6 \text{ cps w\%}^{-1}$) which represents the system sensitivity to carbon.

Determination of soil carbon content (in weight %)

Thus, to determine soil carbon content from the PFTNA measurement for a given area, we need the following:

- defined net INS spectra;
- defined silicon net peak area, SSi_{soil} , and 4.45 MeV net peak area, SC_{soil} , using Gaussian approximations;
- calculated soil carbon content $Cont_{\text{soil}}$ (in w%) using calibration coefficients f and s from the following equation:

$$Cont_{\text{soil}} = \frac{SC_{\text{soil}} - f \cdot SSi_{\text{soil}}}{s} \quad (3)$$

Fig. 9 Carbon calibration dependence. Points with an error bar are data calculated from measurements; straight line is an approximation.

Moisture (hydrogen) calibration dependency

Generally, calibration dependence can be created by parallel measurements of some element content by PFTNA and another method. In the case of hydrogen, the parallel method can be moisture measurements using a nuclear moisture-density gauge. Moisture by this gauge is determined through the detection of thermalized neutrons ('fast' neutrons which have been slowed down by hydrogen present in the material, normally in the form of water). The ^{241}Am —Be radioisotope is used in this gauge as a neutron source. The net hydrogen peak area measured by the PFTNA method compared to moisture measured by the nuclear moisture-density gauge is shown in Fig. 10. Measurements at several locations in the field plot are collected. As can be seen, the dependence of the net hydrogen peak area with moisture is not linear and can be approximated by a parabola. Super linear increasing of the hydrogen peak area can be explained by the increasing number of hydrogen nuclei and the simultaneous increase in thermalization of fast neutrons with increasing moisture. The reversible function of the parabolic fitting function can be taken as the calibration dependence for calculating soil moisture from the net hydrogen peak area.

Fig. 10 The net hydrogen peak area vs moisture measured by Troxler 3440 moisture gauge.

Comparison of PFTNA and chemical analysis (dry combustion) data

Verification of determinations of soil elemental content by the PFTNA method was done by assessing carbon levels by traditional methods. For this purpose, three to five soil cores (4 cm in diameter $\times$ 30 cm in length) were taken around the center of each position in the field where PFTNA measurements (in static mode) were conducted. All cores were divided into 10-cm increments, sieved (2 mm), and oven-dried at 55 °C until constant weight. Subsamples were ground with a roller grinder and analyzed by the dry combustion technique (LECO TruSpec CN analyzer, LECO Corp., Saint Joseph, MI) to determine soil carbon concentration in percent by weight. Results of carbon content measurements by the two methods (dry combustion and PFTNA; average weight percent in the upper 10-cm soil layer and its standard deviation) are shown in Table 2. For clarity, the data are also shown in Fig. 11. These data demonstrate good agreement between both methods, especially for average values for the whole field. It should be noted that the accuracy of the carbon concentration measurement using PFTNA is no worse than that of the dry combustion method.

Methodology of field PFTNA measurements

Soil volume associated with PFTNA measurements

Soil irradiation by fast neutrons excites soil nuclei in some given volume. Relaxation of these nuclei produces the gamma response. The measurement and analysis of these gamma rays provides information on the elemental content in the excited volume. Computer simulations of the 14.1 MeV neutron propagation in soil using MCNP code (MCNP 5, 2007) showed that 90% of the gamma rays hit the detector in an approximately ellipsoidal shaped volume of $\sim 0.22 \text{ m}^3$ with a footprint of 2.1 m^2 ($r \approx 0.8 \text{ m}$) and a depth of 24 cm, while 99% of gamma rays hit the detector from a soil volume that is 3.5 times larger (Wielopolski, 2011). In this simulation, the soil element (nuclei) distribution was taken as uniform. Thus, in real measurements of soil with uniformly distributed elements (nuclei), the gamma response (peak area of some nuclei in gamma spectra) can be attributed to the corresponding average elemental content (i.e., weight percent) in the indicated volume. In some cases, element distribution with soil depth is not uniform. For instance, a carbon depth profile can be described as exponential with a two-fold decrease at 10–15 cm (Wielopolski, 2011). In such cases, the result of measuring the gamma peak area of some nuclei (for instance peak with centroid 4.44 MeV for ^{12}C) can be attributed, as was demonstrated by Yakubova et al. (2017a, 2017b), to the average carbon content in the upper 10-cm soil layer (in weight percent) independent of the depth distribution shape. Thus, PFTNA carbon content measurements are attributed to the average carbon content (in weight percent) in the upper 10-cm soil layer.

The PFTNA measurement time

Two main factors have an effect on the accuracy of determinations of average soil element content for some given volume. There are statistical errors associated with gamma counts acquired in the peak of interest, and random variation in soil elemental content across short distances (decimeters to meters). The average elemental content in soil and cross-section values of neutron interaction affects the statistical error. A suitable value of this error component can be adjusted by selecting the measurement time. To eliminate measurement uncertainty associated with short-range elemental distribution in non-homogeneous soil, measurements can be conducted in the scanning mode with the measurement system moving slowly (4–8 km per hour) across the field. Error analysis of static and scanning measurement results indicates (Kavetskiy et al., 2019) that scanning measurements can be conducted with the same accuracy as static measurements in approximately a quarter of the time. For example, to obtain results analogous to traditional chemical analyses in the case of carbon [i.e., ± 0.26 (95%) w%], scanning time over a given site should be ca. 15 min using the current measurement system configuration. For other elements with higher content and neutron interaction cross-sections, measurement time can be significantly less.

Acquiring data for elemental mapping

In addition to short distance variations in elemental contents, long-range (hundred to thousand meters) variations can also occur. Long-range trends of changing elemental content are of interest when mapping soil elemental distribution for agricultural purposes. Elemental distribution on maps can be represented as isolines overlaying a geographical map of the studied field. Data suitable for mapping should be prepared as datasets of geographical coordinates and corresponding elemental contents. Isolines across the field can be created from such datasets by different methods (e.g., kriging, local polynomial interpolation) using available software e.g., ArcMap (2018).

The mapping procedure can be as follows. The measurement system moves across the field while simultaneously measuring the gamma spectra. Acquired gamma spectra and geographical coordinates of the measurement system's position are saved every 30 s ($\sim 50 \text{ m}$ of travel). The travel track across the surveyed field should approximately ensure even coverage of the field. To accomplish this, the field is virtually divided into sites of approximately equal area. The size of each of these sites should be about 10 times more than the area covered for one measurement (30 s or $\sim 50 \text{ m}$ of travel covered an area $\sim 150 \text{ m}^2$). The system should measure each site for a defined time. For example, if a 5 min defined time is used, the 10 spectra measured within each site will be saved and used for the elemental measurement in that area. During data processing, the difference between two sequentially recorded spectra and geographical coordinate midpoints of where they were recorded are determined and the differential spectral measurements (midpoints spectra) are assigned to these midpoints.

In addition, there are two possibilities that may occur. If the error of determination of the net peak area of interest from the midpoint spectra is more than 10% (like in case of carbon), these midpoints spectra should be sorted and summarized by site. The net elemental peak area and elemental content should be determined from this summary site spectrum. Geographical coordinates of points (attributed to the determined value) are defined as a weighted position of midpoint coordinates attributed to this site. This database (contents-coordinates) will be used for mapping. The number of records in the data base will be equal to the number of sites. On the other hand, if elemental content and neutron interaction cross-section is such that errors of determination of net peak area from midpoint spectra are no more than 5–10% (cases of hydrogen, silicon), site sorting is not required. The net peak area and determination of elemental content can be done using the midpoint spectra. In this data base, the number of records will be equal to the number of midpoints.

If the purpose of soil elemental analysis is to determine the average elemental content of a given surveyed field (e.g., average carbon content for carbon credits), this value can be defined from spectra of the last record of the field scan. In this case, the total

time of the field survey should be no less than 2 h. In this case, the scanning path should eventually cover the whole field. This can be done by virtually dividing the field into equal site areas and scanning each site for the same amount of time. Under this condition, the carbon value returned from the last recorded spectra gives the average carbon content for the whole field.

Determination of total field soil carbon content for 10- and 30-cm layers

The total carbon content in the upper 10 or 30 cm soil layer of a surveyed field can be defined from PFTNA measurement results. Knowledge of these can be useful in carbon credit programs. In addition to PFTNA data of carbon content (in w%), field soil density (d in kg m^{-3}) is required. Total field soil carbon in the 10 cm layer (TC10, t) can be determined according to following equation:

$$TC10 = \sum_{i=1}^n \frac{Cont_{\text{soil } i}}{100} \cdot d_i \cdot S_i \cdot \frac{0.1}{1000}, \quad (4)$$

where n is the number of sites in a divided field for PFTNA measurements, $Cont_{\text{soil } i}$ and d_i , S_i are soil carbon content (w%), soil density (kg m^{-3}) and area (m^2) of the i -th site, respectively. Area can be taken from the computer software that divided the field into sites. Given that the PFTNA measurement result is an average soil carbon content for the field, $\overline{Cont_{\text{soil}}}$, then:

$$TC10 = \frac{\overline{Cont_{\text{soil}}}}{100} \cdot \overline{d_{\text{field}}} \cdot S_{\text{field}} \cdot \frac{0.1}{1000}, \quad (5)$$

where $\overline{d_{\text{field}}}$, S_{field} are average field soil density (kg m^{-3}) and field area (m^2), respectively.

As can be seen from these equations, the soil density value is required for determining the mass of carbon in soil. The nuclear moisture-density gauge is a suitable instrument for soil density determinations under field conditions. This instrument does not require soil sampling and laboratory processing. With this device, a radioactive ^{137}Cs source is inserted to a desired depth based on a previously prepared narrow channel in the soil, and the soil density is defined from the gamma flux attenuation as it propagates through the soil. The measurement procedure for the nuclear moisture-density gauge (e.g., Troxler Model 3440) is relatively easy, and one measurement that takes 1 min can be done in parallel with PFTNA scanning. For these reasons, the nuclear moisture-density gauge was used for soil density determinations. Also note that by using available computer codes (e.g., Google Earth), the area of sites, S_i , or area of field, S_{field} , can be easily defined with good accuracy.

Total carbon content in the upper 30-cm soil layer of the surveyed field (TC30, t) can be defined as

$$TC30 = \frac{TC10}{0.65}, \quad (6)$$

where the coefficient 0.65 is the ratio of the carbon surface density, g cm^{-2} , in the 10-cm layer to the carbon surface density in the 30-cm layer with an error ± 0.10 . This coefficient was found to be an average value for different carbon depth profiles for several agricultural fields in Alabama. As previously discussed, carbon depth profile data were determined using traditional chemical and mass analysis.

Soil elemental field distribution maps

As mentioned above, the main purpose of the PFTNA agricultural field survey was to create a soil elemental distribution map that would be useful in assessing modern agricultural practices, or for defining total carbon content in the 30-cm soil layer for carbon credit purposes. Let us consider examples of such maps.

Soil carbon content distribution map

A soil carbon distribution map of an agricultural field in Alabama (Lee County) is shown in Fig. 12. A scanning survey of this field was conducted to create this map. Movement tracks of the measuring system are illustrated by thin black lines (Fig. 12). Small black points mark places where spectra were recorded at 30-s intervals. A total of 867 records were acquired during this scanning, and the total survey time was 7.2 h. The white polygons are the virtual sites with approximately equal areas. The measurement system spent about the same amount of time at each site. After determining the midpoint spectra and midpoint coordinates between neighboring recorded spectra, data were sorted by sites and summary spectra for each site were determined. At sorting, 33–35 midpoints were attributed to each site. Associated carbon contents in upper 10-cm soil layer were calculated from summary spectra and attributed to one point in each site. These points are weighted centers of midpoints attributed to sites. They are marked by black triangles with yellow values being carbon content. Using this data base (carbon contents and their weighted centers), the carbon distribution map was created. A local polynomial interpolation method with a kernel function polynomial (of the order of 5) in ArcMap software was used. Black lines are isolines of carbon distribution and digits on these black lines denote carbon content in weight percent. Isolines are plotted using increments of 0.25 w%. As can be seen from this map, the variation in carbon content across this field is small. Some decrease in carbon content from northeast to southwest can be observed. This map can be used for assessing agricultural practices (e.g., conventional tillage vs no-tillage practices, row crop sequence, cover crop usage, pasture management, etc.).

Fig. 12 Map of soil carbon distribution in an agricultural field in Alabama.

Using the defined average weight percent of carbon at each site at 10-cm depth, the total carbon content in the 30-cm soil layer over this field can be calculated using Eq. (6). This value was equal to 860 ± 100 (95%) t. From the last record, the average carbon weight percent for the whole field was 1.75 ± 0.28 (95%) w%, and the total carbon content in the 30-cm soil layer was 900 ± 300 (95%) t. Considering limits of error, values of total carbon content determined by each method are in accord, but the accuracy of the first method is much better than that of the second method. Thus, the first method for determining total field carbon content is preferable while the second method can be used for approximate estimates.

Map of moisture distribution

A map of moisture distribution for an agricultural field in Alabama is shown in Fig. 13. This map was created using a dataset consisting of midpoint coordinates and moisture defined from midpoints spectra acquired from each 30-s measurement. To acquire information for this dataset, the field was divided into virtual sites of equal area which provided uniform coverage of the field from scanning paths. Again, the local polynomial interpolation method with a kernel function polynomial of the order of 5 in ArcMap software was used for mapping. The black points on the map mark midpoint positions to which were attributed defined values of moisture. The black lines with digits are isolines showing constant levels of moisture with digits denoting moisture in percent.

Fig. 13 Map of moisture distribution for an agricultural field in Alabama.

Isolines were plotted with moisture steps of 2%. As can be seen from this map, practically all field values of moisture are ~16% and there is only a slight decrease in moisture in the south-east corner. This map can be used for assessing agricultural practices. Naturally, this moisture map is representative for the date of survey and will change as weather conditions change over time.

Conclusion

Applications of neutron-gamma analysis both in soil science and in assessing agricultural practices in terms of soil elemental determinations can serve as an alternative to traditional chemical analysis. This method is based on measuring the gamma ray response that appears by irradiating objects of interest, in particular soil, by fast neutrons. This method of soil elemental analysis has advantages over traditional laboratory chemical methods. This is a nondestructive *in situ* method of analysis that requires no sample preparation and can perform simultaneous multi-elemental analyses of primary soil elements (Si, C, O, H—moisture, Fe) in large soil volumes. Importantly, measurements are negligibly affected by local sharp changes in elemental content. The accuracy of soil elemental content determinations by the neutron-gamma method is no worse than chemical analysis as was shown in the soil carbon example. These advantages support use of the neutron-gamma method in soil science and for assessing agricultural practices.

The Pulsed Fast/Thermal Neutron Analysis (PFTNA) is a modification of neutron-gamma analysis of soil that applies both static and scanning modes. This method, paired with GPS, presents the possibility of acquiring a data set suitable for creating *in situ* maps of elemental distribution. Together with the nuclear method of the determination of field soil density (e.g., Troxler 3440), the PFTNA can be applied to define total soil carbon in fields. Despite some error (10 or even 30% at 95% confidence level), acquired data can be used for carbon credit estimates.

Modifications of neutron-gamma analysis such as the tagged neutron method or associated particle imaging (API) method are promising directions for *in situ* determination of soil elements. The better signal-to-noise ratio of the API method (compared to PFTNA) can decrease the measurement time required to reach desirable accuracy. Further development of this method for applications in soil science and agriculture is currently underway.

Abstract

Since the discovery of single-crystal X-ray diffraction (XRD), various X-ray diffractometers have been developed and utilized for the identification, characterization and quantification of soil components because of their convenience, efficiency, accuracy and non-destruction. Amongst soil components, soil minerals often act as an indicator of diagenesis in soil, which can be identified and quantified by XRD techniques. Basic principles, methodology and instrumentation of XRD and factors affecting the XRD signal strength are described in this chapter. Moreover, the application of XRD in soil analysis is revealed, especially for soil mineral qualification, soil mineral quantification and soil evolution.

Key points

- Basic principles, methodology and instrumentation of XRD are introduced.
- Factors affecting the XRD signal strength are summarized.
- Soil mineral qualification is studied using XRD.
- XRD-based technique is employed to quantify soil minerals.
- XRD is applied in the investigation of Soil Evolution.

Introduction

Since the single-crystal X-ray diffraction (XRD) was discovered by von Laue in 1912 (Ballon et al., 1983), various X-ray diffractometers have been developed, for example the, Debye-Scherrer-Hull diffractometer, Seemann-Bohlin diffractometer and the most well-known Bragg-Brentano diffractometer (Brentano, 1946; de Wolff, 1948; Guinebreiere et al., 2005). When a substance (crystalline or amorphous) is subjected to diffraction analysis, the sample is irradiated by X-rays to produce different degrees of diffraction (Arndt, 1986). Based on the unique diffraction pattern, the composition, crystal form, intramolecular bonds and molecular configuration can be determined. Due to the convenience, efficiency, accuracy and non-destructive testing, X-ray diffraction has been widely utilized as a definitive technique for the identification, characterization and even quantification of soil components (Barre et al., 2007; Bunaciu et al., 2015; de Araújo et al., 2021).

Soil minerals, including soil primary and secondary mineral, is one of the most important soil components (Lin et al., 2017; Zhang et al., 2006). Soil primary minerals are referred to as substances formed directly from parent rocks, which have undergone different degrees of physical weathering, but with no changes in their chemical components and crystal structures (Liu et al., 2019). Secondary soil minerals are new minerals transformed or generated from primary minerals through chemical or biological processes, which include various simple salts, secondary oxides and aluminosilicate minerals (Liu et al., 2019). Notably,

aluminosilicate minerals, commonly known as clay minerals, are important soil secondary minerals with complex crystal structures. Clay minerals are often used as indicators of diagenesis in soil. For most soil environments, several types of clay (e.g., kaolinite, chlorite, smectite, illite and mica) commonly coexist either within discrete phases or as mixed-layer minerals in which different types of clay layers coexist in the same crystal (Viennet et al., 2015; Zhang et al., 2017). Over the past decades, XRD techniques have been widely used to identify and quantify clay minerals (Han et al., 2014; Ndzana et al., 2019).

Basic principles, methodology and instrumentation

X-ray

An X-ray is a kind of electromagnetic wave with short wavelength (about 0.06–20 Å), which can penetrate a certain thickness of materials, and can make fluorescent materials emit light and induce gas ionization (Gabriel, 1977). When bombarding a metal target with an electron beam, X-rays with specific wavelengths are produced and correspond to various elements in the target, which are termed as characteristic X-rays. The essence of the X-ray is a kind of electromagnetic wave that possesses wave-particle duality. X-rays are characterized by their waviness as they travel in space at certain wavelength and frequencies. Generally, X-rays have wavelengths in the range of 0.01–100 Å, which are between γ and ultraviolet rays.

By stopping fast-moving electrons or ions suddenly, the kinetic energy of the electrons can be partially converted into X-ray energy, thus emitting X-rays. When a beam of high-speed electrons bombards a metal target, the X-ray tube produces two different kinds of X-rays, corresponding to characteristic and continuous X-rays, respectively. Moreover, characteristic and continuous X-rays have different properties, mechanisms and uses.

X-ray diffraction

An important application of X-rays is for X-ray diffraction (XRD) analysis, in which characteristic X-rays are used. The XRD is a method of research in which the diffraction pattern of a material is analyzed to obtain information about its structure, composition or atomic/molecular morphology inside it. It is used to determine the crystal structure, which causes the incident X-ray beam to diffract in many specific directions. By measuring the angles and intensities of these diffracted beams, crystallographers can produce a three-dimensional image of the electron density within the crystal. From the information, the average positions of the atoms in the crystal, as well as the chemical bonds can be determined.

Different atoms lead to various outer electron configurations, so different target materials have different X-ray characteristic wavelengths. The X-rays generated by the target material with a short wavelength are termed short-wavelength target X-rays, while long-wavelength target X-rays refer to those produced by the target material with a long wavelength. The peak of the diffraction pattern is regularly expressed along the 2θ axis when using the short-wavelength target X-ray. While, stretched peaks along the 2θ axis are obtained by using the long-wavelength target X-ray. Notably, the sample surface spacing d value obtained from the diffraction pattern is the same and independent of the target no matter what kind of target X-ray tube is used.

The diffraction peak strength depends strongly on the crystal structure, while the mass absorption coefficient (MAC) of the sample is mainly related to the wavelength of the incident ray. Therefore, the diffraction peak intensity of the same sample obtained with different X-ray sources would be slightly different. In particular, for mixed samples, the MACs between the items vary with the selected wavelength. Therefore, improper selection of X-ray wavelength may lead to inaccurate quantification of the components by XRD.

Since MAC mutations for different elements have varied wavelengths, the wavelength range is termed the absorption limit, and strong scattering fluorescence would occur when exceeding this range. As a result, the atomic numbers of the elements in the sample are generally 1–4 times smaller than that of the target element. For example, it is appropriate to use an iron (Fe) target for the analysis of a substance mainly composed of iron, cobalt (Co) and nickel (Ni), but this is not suitable for a sample containing elements of manganese (Mn), chromium (Cr), vanadium (V) and titanium (Ti).

The Bragg equation

The Bragg equation, $2d\sin\theta = n\lambda$, is the basic rule for X-ray diffraction in crystal analysis. It reflects the relationship between the crystal structure and the direction of the diffraction line. In the formula, θ , d , n , λ and 2θ are the incident angle, crystal plane spacing, diffraction order, wavelength of the incident ray and the diffraction angle, respectively (Fig. 1). The crystal spacing, d , depends on the interference index and cell type, indicating cell shape and size, which can be deduced by the Bragg diffraction angle determined to establish the relationship between the diffraction pattern and the crystal structure.

According to the above Bragg equation, if the X-ray satisfies the crystal plane, X-ray diffraction intensity will be strengthened. Therefore, when the reflection rays of different crystal faces are strengthened, it means that the difference in distance between the reflection rays of adjacent crystal faces is an integral multiple of the wavelength.

The Bragg equation is applied as below. When the d value of the crystal is known, the λ value of the characteristic X-ray can be calculated by measuring the θ value. Also, the element that produces the characteristic X-ray can be deduced based on the

Fig. 1 Schematic diagram of the Bragg equation. Adapted with permission from Bunaciu AA, Udristioiu EG and Aboul-Enein HY (2015) X-ray diffraction: Instrumentation and applications. *Critical Reviews in Analytical Chemistry* **45**: 289–299.

λ value determined. Moreover, given the wavelength λ of the incident X-ray, the spacing d between the surface and the network can be determined by measuring θ . As a result, the crystal structure is determined or the phase is analyzed by the distance between the surface and the net.

Instrumentation

Fig. 2 shows that an X-ray diffractometer contains three basic elements: an X-ray tube, a sample holder and an X-ray detector. The X-rays are generated in a cathode ray tube, in which electrons are initially produced by heating a filament, and accelerated by the applied voltage to bombard the target material. When the generated electrons have enough energy to move the electrons out of the inner shell of the target material, characteristic X-ray spectra are produced. These spectra consist of several components, including K_α and K_β , where, K_α is composed of $K_{\alpha 1}$ and $K_{\alpha 2}$ to some extent. The wavelength of $K_{\alpha 1}$ is slightly shorter and the intensity is twice that of $K_{\alpha 2}$. The specific wavelength is a feature of the target material, e.g., copper (Cu), iron, molybdenum (Mo), chromium. By filtering the X-rays through a foil or crystal monochromator, monochromatic X-rays required for diffraction analysis can be generated. The $K_{\alpha 1}$ and $K_{\alpha 2}$ have similar wavelengths, so the weighted average of the two parameters (K_α) is used. The wavelength of the X-ray can be adjusted by changing the material of the anode target of the X-ray tube, and the intensity of the X-ray source can be controlled by varying the anode voltage and the current of the X-ray tube. Copper is the most commonly used target material for single-crystal diffraction, whose K_α radiation equals to 1.5418 Å.

The sample holder is located at the center of the goniometer circle and can be rotated around the central axis. The goniometer is an instrument used to maintain the angle and rotate the sample, while, the X-ray detector is installed on the circumference of the goniometer and can also be rotated around the central axis. To ensure that the detector is always in the reflection direction, the detector and the sample stage rotate at the same time. For instance, the sample is rotated at an angle of θ on the path of the collimated X-ray beam, while the X-ray detector is mounted on an arm and is rotated at an angle of 2θ . Then the diffracted X-ray signals are collected by recording the reflected X-ray intensity. An intensity peak appears when the geometry of the incident X-ray satisfies the Bragg equation and constructive interference occurs. Finally, the detector will record and process the X-ray signals, and the results are converted into the count rate of photons, which is subsequently output to devices such as a printer or computer monitor.

Fig. 3 illustrates the geometric arrangement known as the Bragg-Brentano para-focusing system, which includes a system source (F), Soller slits (P and RP), sample (S), divergence slit (D), and receiving slit (R). Line A is the axis of the goniometer and distances FA and AR are equal. In the system, the line source F emits a diverging beam, falling on sample S. After being diffracted, the light beam reaches the detector through the receiving slit R. The effective focal length of the light source F and the aperture of the divergence slit D determine the amount of divergence. The axial divergence is controlled by two Soller slits (sets of parallel plate collimators, P and RP) between F and A, and A and SS, respectively. The use of a narrower divergence slit will give a smaller sample coverage at a specific diffraction angle, thereby allowing a lower diffraction angle to be obtained when the sample has a larger apparent surface, which is indicative of a larger θ value. However, this can only be achieved at the expense of lower intensity. Therefore, the choice of divergence slit and its matching scatter slit is determined by the range of angles covered. It depends strongly on the intensity available to decide whether to increase the size of the slit at a given angle. The diffracted X-ray photons will be converted into voltage pulses by a photon detector, commonly a scintillation detector, which is placed behind the scatter slit. These pulses can be integrated in a rate meter, giving an analog signal on the x/t recorder, with which the scanning speed of the goniometer is synchronized, and a plot of the relationship between 2θ degrees and intensity (i.e., diffractogram) can be obtained.

Most of the basic geometric issues of diffractometers were pointed out around 2000. The width of the diffraction line is reduced by the introduction of the focusing geometry, which corresponds to the improvement in instrument resolution function (IRF). The IRF is an important driving force in the competition between X-ray diffractometer manufacturers. Besides IRF, the pattern acquisition time is another important aspect. In addition to the detector and X-ray source, the geometry of the diffractometer also affects the reduction in pattern acquisition time. In general, reducing the pattern acquisition time and improving IRF are conflicting choices. Therefore, the design of the diffractometer aims to achieve a good compromise between the two factors. Based on this, X-ray diffractometers have been developed in different directions, satisfying different purposes. However, no diffractometer is suitable for all measurements. Therefore, it is necessary to select a convenient instrument when solving scientific or technical problems.

Intensity of the diffraction line

The Bragg equation determines the direction of the diffraction line, relating it to the fundamental period of crystal structures. By measuring the diffraction direction, the symmetry type and cell properties, the crystal structure can be determined theoretically, but not the type and position of the atom arrangement.

Furthermore, the element and the atomic position in the crystal determine the diffraction intensity of the X-ray. While, the diffraction pattern depends on the intensity of the diffraction line. There are three basic elements in the diffraction pattern, i.e., the shape, peak position and intensity of the diffraction line. The diffraction intensity can be divided into integral intensity and peak height intensity. The latter corresponds to the intensity related to the peak height of the diffraction line, while the integral strength is the area below the curve and above the base. The expression for the diffraction line intensity of a substance is complex, but it can be written concisely in the following equation (Eq. 1):

$$I = I_0 \times K \times |F|^2, \quad (1)$$

where, I_0 is the monochromatic X-ray incident intensity on a unit cross-section area, F is the structure factor that depends on the crystal structure and the properties of the atoms contained in the crystal, K is a comprehensive factor, including diffraction geometry conditions, the shape and absorption properties of the samples, as well as physical constants during the experiment (e.g., temperature).

Factors affecting the XRD signal strength

Regardless of the mutual interference between incoming rays, scattered rays and the re-scattering phenomenon of the scattered waves, if the research object is an ideal polycrystal, with neither coarse grains nor preferential orientation and with uniform and continuous diffraction rings, under this condition the cumulative intensity I_{hkl} of the diffraction ring per unit length is calculated by the following formula (Eq. 2):

$$I_{hkl} = \frac{I_0}{32\pi R} \left(\frac{\mu_0}{4\pi} \right)^2 \left(\frac{e^2}{m} \right)^2 \lambda^3 (N^2 |F_{hkl}|^2 P_{hkl}) (L_p) (e^{-2M}) [A(\theta)] V, \quad (2)$$

where, e is electronic charge, m is electronic quality, N is the number of unit cells per unit volume, I_0 is the intensity of incident X-ray, λ is the X-ray wavelength, R is the distance between the diffraction line, μ_0 is the line absorption coefficient, hkl is indice of crystallographic plane, F_{hkl} represents the structural factor, p_{hkl} is the multiplicity factor, L_p is the angle factor, e^{-2M} is the temperature factor, $A(\theta)$ is the absorption factor, and V is the volume fraction of the diffracted object.

According to the above formula, the direction and intensity of the diffraction depend on the internal structure of the crystal (e.g., the type, number and arrangement of atoms in the unit cell, etc.) and its periodicity. In the same phase, the factors that affect the diffraction intensity include the degree of crystallinity of the sample (influencing the shape of the diffraction peak), purity (influencing the resolution), the fineness of the powder sample (when the θ value is the same, the absorption is different), and the radiation wavelength (in the d value phase). Meanwhile, the angle factor $\varphi(\theta)$ is different, and the preparation conditions of the powder sample (preferred orientation should be considered) also affect the diffraction pattern. Different test methods will also cause different diffraction intensities.

The XRD analysis for soil mineral qualification

The XRD techniques have been widely applied to analyze soil samples in many fields. As the most fundamental function, the technique is used to identify the components of soil samples. The components can be identified by the 2θ values and intensity of peaks according to the PDF (powder diffraction file) cards of standard samples or previous research. In most cases, for natural soil samples, the signals of quartz and clay dominate the XRD patterns because of their good crystal structures and large contents in soil. However, by analyzing the different positions and intensities of the peaks, interesting results can be obtained, such as the transformation process of minerals and identification of metal or metalloid elements in the samples. By comparing the different XRD patterns of rock samples with increasing weathering, different behaviors of chemical elements can be provided by the dissolution of silicate minerals into the surrounding groundwater system. For example, arsenic geochemistry and mineralogy as a function of particle-size in natural arsenic-enriched soil can be determined via XRD analysis and some other characterization methods. The XRD of soil samples can also assist researchers to discover the soil or ocean condition in paleogeography. On the other hand, minerals present within the soil environment exhibit characteristic crystal structures, chemical compositions and properties that determine the total reserves of essential plant nutrients. Thus, the mineral–nutrient relationships in soils are extensively assessed using cluster analysis of X-ray powder diffraction patterns and compositional methods.

The XRD-based quantification methods for soil minerals

With the complexity of soil components, various strategies have been developed, amongst which three general approaches based on the XRD technique are commonly used for the quantification of soil clay minerals, i.e., methods of known addition, the absorption-diffraction method and mineral intensity factor method (Fig. 4) (Kahle et al., 2002).

Method of known addition

The method of known addition means that known doses of the minerals are added into the sample. By extrapolating to zero, the original content of the phase can be obtained. Therefore, there is a need to consider that how well the added standard minerals match those in the soil samples. The peak intensity is strongly influenced by the structure factors, which are controlled by the atomic positions in the cell unit and the chemical compositions of the minerals. For example, isomorphous replacement of iron in clay minerals has a dominant control on the structure factor. However, the method of known addition is very time-consuming for a soil sample that is composed of several clay mineral phases, and cannot be recommended for researchers with large quantities of samples.

Absorption-diffraction method

The absorption-diffraction method has been used to quantify soil clay minerals, in which the intensities of the diffraction peak i can be determined for phase α in the mixture of unknown composition and in the pure phase, respectively. If both the mass absorption

Fig. 4 Protocols for XRD-based quantification of clay minerals in soil samples. Reproduced with permissions from Kahle M, Kleber M and Jahn R (2002) Review of XRD-based quantitative analyses of clay minerals in soils: The suitability of mineral intensity factors. *Geoderma* **109**: 191–205.

coefficients of the pure phase α and the mixture are available, and the weight fraction of phase α can be determined by comparing the peak intensity ratio. However, this method is probably not suitable for the quantification of clay minerals in oriented aggregates, which could be attributed to inaccurate determination of the variability of preferred orientation between the mixture of unknown composition and the pure phase. It is a matter of fortune to select a standard mineral with diffraction characteristics identical to those of the mineral in the sample, which is similar to the method of known addition.

So far, the absorption-diffraction method and mineral intensity factors have been the most commonly used approaches for XRD-based quantification of soil minerals. The general relationship between the weight fraction of a mineral and the integrated intensity of a diffraction peak is simplified in the following equation (Eq. 3):

$$I = W(1/V^2)(1/\rho)IFl^2PL\psi(1/\mu)K \quad (3)$$

where I , W , V^2 , ρ , IFl^2 , P , L , ψ , μ and K refer to the integrated intensity of a diffraction peak, the weight fraction of the mineral, volume of the unit cell, density of the mineral, structure factor, polarization factor, Lorentz factor, powder ring distribution factor,

mean mass absorption coefficient of the mineral mixture and a constant, respectively. For a specific diffraction peak i of a known mineral, V^2 , ρ , IFI^2 , P , L and ψ are supposed to be fixed and the product of these terms can be set as a constant U . As a result, the integrated intensity I_i of the peak i can be simplified as in Eq. (4). Consequently, the peak intensity ratio of two components can be calculated as in Eq. (5) in a given mixture. The ratio of U_α/U_β refers to mineral intensity factor and is also a constant. The proportions of the minerals in a mixture can be calculated if all mineral factors are known in relation to a specific mineral standard.

$$I_i = WU(1/\mu)K \quad (4)$$

$$I_\alpha/I_\beta = (W_\alpha/W_\beta)(U_\alpha/U_\beta) \quad (5)$$

Considering the occurrence of soil clay minerals as a mixture, the signal intensity of each mineral phase in the mixture depends on various physical properties. However, the physical properties are not constants amongst different clay mineral phases, consequently leading to the well-known phenomenon that the relative 001 peak areas of clay minerals in the mixture of equal parts are commonly not equal. Therefore, it is bound to fail for the quantification of clay minerals by referencing individual 001 peak areas to the sum peak areas in a diffractogram.

Mineral intensity factor method

The mineral intensity factor method can follow two different procedures, i.e., the addition of an internal standard and the 100% approach. In the internal standard method, extra internal standards that do not exist in the sample initially are added into it before XRD measurement. The minerals selected as reference internal standards always have the following characteristics: (a) uniform particle size to minimize particle-size segregation when preparing samples; (b) the same crystalline morphology as the unknown minerals in the soil sample; (c) negligible interference with useful diffraction peaks of unknown components; (d) at least one conveniently located strong reflection. For example, pyrophyllite and silicon are commonly recommended as internal standards for the analysis of clay minerals and iron oxide in soil samples, respectively.

The internal standard method can be described theoretically as in the formula below (Eq. 6):

$$x_p = kI_p/I_s \quad (6)$$

where k is a coefficient related to the nature of component P and internal standard s, the properties of the X-ray diffraction test (i.e., the geometry of the apparatus and the wavelength of the X-ray) and the amount added from the standard. x_p is the mass % of component P. The I_p and I_s are X-ray diffraction intensities of component P and the standards, respectively.

Quantification of clay mineral by means of mineral intensity factors consists of two steps. First, the values of mineral intensity factors for phases in a soil sample must be determined using standard mineral mixtures composed of known amounts of the internal standard mineral and one other component. Second, the integrated intensity of the same diffraction peak is measured after adding a known dose of the internal standard with a specific diffraction peak. Quantification of the soil mineral is performed through dividing the integrated intensity of the mineral by the corresponding mineral intensity factors, which is subsequently multiplied with the quotient of the weight fraction.

Considering the presence of short-range-order minerals and non-crystalline materials or misidentified minerals, the sum of the weight fractions of the reference internal standard and soil clay mineral components is commonly not equal to 100%, thus leading to the preference of internal standards from the literature. However, the disadvantages of the internal standard method are related to the difficulty in the selection of standard minerals and the time taken, so another so-called 100% approach has wide application. Suppose that all phases existed in the sample, have been thoroughly identified and the sum of different phase quantities equals to 100%, the weight fraction of each phase (W_α) can then be calculated according to Eq. (7):

$$W_\alpha = (I_\alpha/MIF_\alpha)/\Sigma(I_n/MIF_n) \quad (7)$$

Where I_α and I_n represent the intensities of the selected peaks from phase α and n in the mixture, respectively, MIF_α and MIF_n refer to the mineral intensity factors for phase α and n , respectively.

The application of XRD for soil evolution

Vast areas in the Mediterranean are characterized by evaporite deposits. Large deposits have been built up in a shallow lagoon-like system, which are now widely distributed in Albania, Cyprus, Turkey and southern Italy. These deposits have been extensively investigated for soil formation on evaporites in subarid to arid environments. Although the formation of soil has achieved new significance, little is known about the evolution of the Mediterranean evaporites. Therefore, soil formation is investigated for evaporites collected from the Caltanissetta basin (Sicily, Italy), and the soil profiles with soil horizon designation is shown in Fig. 5. The lithology includes marine clay deposits, laminated marl (diatomite; Tripoli sediments), limestone, detritus deposits and gypsum (selenite). During pedogenesis, element leaching from silicates was the most dominant process in the soil, which was active before the development of clays and the Tripoli sediments. Vertisols and Mollisols evolved together with a large amount of

Fig. 5 The soil profiles with soil horizon designation. The soil profiles of Tripoli 1 from top to bottom refer to A1, A2, C1 and C2; The soil profiles of Argille from top to bottom refer to A, Bss and Bssg. kaolinites and oxyhydroxides (non-crystalline and crystalline forms). Weak soil formation was only recognized at sites containing gypsiferous parent material. The presence of selenite can hinder more advanced evolution. The soils developed on detritus and gypsiferous material that contain some palygorskite, which is inherited from the parent material. Moreover, shallow Aridisols or Mollisols are observed at sites that have limestone or selenite. Weathering is pronounced as indicated by a large proportion of trioctahedral minerals. In addition to inheritance from the parent material, kaolinite and smectite also undergo active formation in the soil as weathering proceeds. Plagioclase and mica are the main sources of smectite, and K-feldspar is the main source of kaolinite neoformation (Egli et al., 2019).

The X-ray diffractograms of typical samples after saturation with glycerol, Mg ions and K ions as well as calcination treatments are shown in Fig. 6. After glycerol saturation, the Tripoli samples exhibit basal reflections at 0.72, ~0.90, 1.00, 1.10 and 1.71 nm. The peak around 1.71 nm suggests the presence of smectite (Fig. 6), while, the peak at 0.91 nm is probably due to a reflection ($d(002)$) of the 1.71 nm peak. The peak at 1.00 nm refers to mica, while the diffraction peaks at 1.08, 1.12 and 1.32 nm are assigned to irregularly interstratified minerals (e.g., mica/smectite) (Fig. 6). However, the peak near 1.08 nm may be assigned to palygorskite. The quantitative analysis of minerals in the clay fraction suggests that a minor content of palygorskite is possibly present in the Tripoli, Argille 7, Calcare and particularly the Gessi samples. The peak at ~1.41 nm (Mg saturation) of the A1 horizon from Tripoli 1 (Fig. 6) remains after K saturation. This peak collapses after heat treatment, indicating the existence of some hydroxy-interlayered-smectite (HIS) or hydroxy-interlayered-vermiculite (HIV). Neither HIS nor HIV can be detected in the C2 horizon of the Tripoli soil, demonstrating that HIV is pedogenically formed. In general, there is no distinct difference in the XRD pattern between the subsoil and topsoil. In the Tripoli soil, some HIV and some additional interstratified clay minerals undergo active formation during pedogenesis, whereas changes observed in the Argille soil were barely recognizable. The Argille soil is affected by vertic processes, leading to a homogenization of the top- and sub-soil. Consequently, the mineralogical differences are minor. Compared to the Tripoli soil, the Argille soil contains a distinctly higher content of kaolinite (Fig. 6), while the Tripoli soil has a larger content of interstratified minerals (Egli et al., 2019).

Evaluation of the XRD patterns of phyllosilicates (58–64 degrees 2θ region) confirms the presence of both trioctahedral and dioctahedral phases of mica in the subsoil and topsoil (Fig. 7). Trioctahedral species are represented by peaks ranging from 59 to 61 degrees, and dioctahedral species are found, correspondingly, in the range of 61–63 degrees 2θ . A significant part of the peaks around 0.1537 and 0.1533 nm can be assigned to quartz. The peaks near 0.1520 nm are, thus, more indicative of changes in trioctahedral species. The proportion of trioctahedral species in the Argille soils seems to decrease during the pedogenesis process (the intensity of peaks around 0.1520 decrease from Argille 6A to Argille 6Bss) (Fig. 7), indicating that the trioctahedral mica undergoes active weathering. The contribution of the peak ranging from 0.1495 to 0.1498 nm (kaolinite and smectite) increases with progressive soil evolution, as indicated by the decrease in peak intensity (0.1495–0.1498 nm) from Tripoli 1C2 to Tripoli 1A1 (Fig. 7). This mica is either transformed into smectite or is an interstratified mica/smectite (Egli et al., 2019).

(2019) Soil development on sediments and evaporites of the Messinian crisis. *CATENA* **187**: 104368.

The XRD has been applied to analyze the relationship between the formation and evolution of soil clay minerals and environment in a terrestrial ecosystem of Northern China (Zhang et al., 2021). Fig. 8 shows the diffraction peaks located at 3.34, 3.54, 4.25, 4.71, 5.00, 7.10, 10.00 and 14.20 Å, which indicate the presence of quartz, illite, kaolinite and vermiculite. Moreover, consistent results of soil minerals were obtained for farmland, wetland and forest. The reflections for quartz are located at 3.34 Å and 4.25 Å, showing a negligible degree of weathering and proving its strong resistance to weathering. The peaks of K-saturated clay mineral remained unchanged after heat treatments at 300 °C and 550 °C, confirming the existence of illite, it's a non-swelling 2:1 type of clay. Fig. 9 shows that the Mg-air (air-dried) samples have a strong diffraction peak at 14.20 Å, but after treatment with glycerin, this reflection disappeared after high temperature calcination. While, the peak at 10.00 Å was strengthened, further confirming the coexistence of vermiculite (Vanderaverroet et al., 2000). Similarly, the 7.10 Å peak of K-air vanished with heat treatment, suggesting that kaolinite also existed.

The strong microbial activity and high degree of weathering in forest soil may make it a better alternative to farmland and wetland soils to represent the soil mineral evolution of a terrestrial ecosystem. By comparison with the conventional XRD method, synchrotron radiation XRD (SR-XRD) possesses various advantages such as small incident spot diameter, high angular resolution,

Fig. 7 Peak separation of X-ray patterns in the $d(060)$ region of some typical soil samples (clay fraction). The peak region ranging from 59 to 61 degrees 2θ can be attributed to trioctahedral minerals and the region between 61 degrees and 63 degrees 2θ to dioctahedral species. Adapted with permission from Egli M, Plötze M, Tikhomirov D et al. (2019) Soil development on sediments and evaporites of the Messinian crisis. *CATENA* **187**: 104368.

strong brightness and penetration, thus exhibiting great improvements in the accuracy of soil morphology characterization in both depth and breadth (Christensen et al., 1996; Gualtieri et al., 1996; Cheng et al., 2017). Fig. 9 shows that the diffraction peaks are more concentrated and their intensity is greater than those of conventional XRD. Moreover, SR-XRD produced higher resolution and narrower diffraction peaks for the same scanning range. For instance, the peak at 3.34 Å (referring to illite) is compact in the SR-XRD spectrum, indicating the crystallinity better. Moreover, the diffraction peak was negligible in the conventional XRD spectra, while the reflection signal obtained in the SR-XRD spectra is clear (Figs. 8 and 9). By comparison with conventional XRD spectra, there is a slight turning point at 12.20 Å for the SR-XRD spectra, which subsequently rises rapidly to 14.10 Å. This suggests that a mixed layered mineral of illite and vermiculite might exist and the diffraction peak at 14.10 Å was probably derived from HIV. In addition, the high diffraction peak at 3.19 Å confirms the presence of plagioclase in Fig. 9. Therefore, SR-XRD could serve as an alternative to achieve a more accurate and reliable analysis of clay minerals compared with the conventional XRD.

Conclusion

In this chapter we have provided a detailed introduction of XRD, including the basic principles, methodology, instrumentation, influencing factors and applications. Amongst the wide applications, the XRD-based technique was specifically summarized for soil analysis, i.e., XRD analysis for soil mineral qualification, XRD-based methods of quantification for soil minerals and application of XRD for soil evolution. Furthermore, based on the XRD results, the activity of weathering processes at different soil depths can be

Fig. 8 The X-ray diffraction spectra of clay minerals in farmland (A), wetland (B) and forest (C). K-air and Mg-air refer to air-dried samples saturated with K and Mg ions, respectively. K-300 and K-550 correspond to K-saturated samples oven-dried at 300 °C and 550 °C, respectively. Mg-gly refers to Mg-saturated and glycerin-treated samples. deduced by comparing the content of minerals. Generally, XRD is an efficient method for qualitative and quantitative analysis of soil components, thus providing further information about mineral transformation processes. Therefore, XRD processing will make greater contributions to promote the development of soil and environmental sciences in the future. By comparison with conventional XRD, SR-XRD can act as an alternative to achieve a more accurate and reliable analysis of clay minerals given its advantages such as small incident spot diameter, high angular resolution, strong brightness and penetration.

Abstract

Analyses of soil physicochemical properties, including texture, carbon (C) content, and plant nutrients, are essential for effective farm management. However, because they require several time-consuming and expensive methods, such analyses are not viable on a large scale, as in precision agriculture. An attractive alternative to these methods is laser-induced breakdown spectroscopy (LIBS), which provides quick, affordable, and simultaneous assessments of several soil characteristics. This chapter covers the latest advances in LIBS for assessing toxic elements, plant nutrients, C content, and physicochemical properties of soils. The benefits and limitations of LIBS, compared to conventional methods, will be discussed for each assessment.

Glossary

ICP-MS Inductively coupled plasma mass spectrometry
ICP-OES Inductively coupled plasma optical emission spectrometry
LIBS Laser-induced breakdown spectroscopy
LOD Limit of detection
Nd:YAG laser Neodymium-doped yttrium aluminum garnet laser

Key points

- LIBS is an alternative, attractive method for soil analysis;
- LIBS has advantages over conventional methods for soil analyses involving a large number of samples;
- LIBS provides rapid soil analyses with minimal sample preparation, no generation of residues, and simultaneous assessment of several physicochemical properties;
- The main limitations of LIBS in soil analysis are (1) matrix effects and (2) the high LOD values for elements such as N, P, S, Cl, B, Ni, and Zn;
- LIBS can assess, with decent accuracy, plant nutrients, toxic elements, and physicochemical properties;
- Verra has qualified LIBS as a valid method to support soil carbon certification;
- Further studies in LIBS are required to improve the quantification of certain plant nutrients (e.g., N, P, S, Cl, B) and toxic elements (Ni and Zn) in soil samples;

Introduction

Understanding the physicochemical characteristics of soils is crucial for farmers as it enables them to make informed and strategic decisions about farm management. By optimizing the use of inputs and minimizing environmental impacts, farmers can enhance productivity and meet the ever-increasing global demand for food. However, analyzing soil characteristics requires several techniques that are typically time-consuming, expensive, and environmentally unfriendly, as they generate toxic residues. So,

how can soil samples be reliably and promptly analyzed? The solution is the development of new technologies and instruments that give farmers access to soil characteristics rapidly, affordably, and with adequate accuracy and precision. Laser-induced breakdown spectroscopy (LIBS), which requires a single measurement, is an attractive technique that meets these criteria. Recent studies and reviews (Tavares et al., 2022; Villas-Boas et al., 2020a,b) suggest that LIBS can rapidly assess various soil properties such as texture, pH, carbon (C) content, and cation exchange capacity, in addition to the concentration of plant nutrients and toxic elements.

LIBS is a spectroanalytical technique capable of simultaneously identifying and quantifying any element on the periodic table (Cremers and Radziemski, 2013). LIBS analysis takes less than 1 min per sample and can be performed under ambient air atmospheric conditions. This technique requires a simple experimental setup with, at least, five components: a pulsed laser, a focusing lens, an emission collection optical system, a spectrometer, and a delay generator (Fig. 1). By focusing the laser pulse on the sample surface, molecular bonds are broken, and atoms and ions are heated, thus generating a plasma plume with temperatures that can exceed 50,000 K. After a few microseconds, the background emission decreases, at which time the spectrometer gate is opened to acquire the LIBS emission spectrum. By examining the resulting spectrum, the analyst can recognize the elements contained in the sample through their atomic and ionic emissions. The intensity of these emissions, which is usually obtained from the height or area of the lines, reflects the total concentration of the elements and is used in LIBS quantitative models. The bioavailable nutrient content and physicochemical properties of soils can be inferred from the entire spectrum or from the intensity of selected emission lines by multivariate machine learning models.

LIBS offers several advantages compared to traditional methods of soil property analyses. These advantages are: (i) minimal sample preparation since it allows for the direct analysis of solid samples in the form of pellets; (ii) small amount of material required for the samples undergoing analysis (around 0.5 g per sample measurement, depending on the sample and laser characteristics); (iii) simultaneous multielement determinations, including plant nutrients and toxic elements; (iv) high analytical frequency (spectral acquisition within less than 1 ms); (v) no need for chemical reagents; (vi) no generation of post-analysis chemical residues; and (vii) possibility of direct in situ soil analysis with a portable system, without the need to collect and transport the samples to the laboratory. In comparison to other analytical techniques, soil sample preparation for LIBS analysis is relatively simple, and includes sample homogenization using pestle and mortar or an automatic mechanical grinder, sample pelleting, and LIBS analysis (Fig. 2).

LIBS has not yet become a routine technique for laboratory soil analysis due to two key disadvantages (i) matrix effects and (ii) poor limit of detection (LOD) for some plant nutrients and toxic elements. The first disadvantage results from the fact that the LIBS signal depends not only on element concentration, but also on the sample's physicochemical properties, such as chemical composition, light absorption coefficient, and thermal conductivity (Borduchi et al., 2022). Because of matrix effects, developing quantitative models for samples of various composition, especially soils, is challenging. To mitigate matrix effects in soil analyses, several strategies can be used, such as the use of femtosecond or picosecond lasers, ultraviolet laser pulses, spectral pre-processing

Fig. 1 Overview of soil analysis and the possible determinations using the LIBS technique.

Fig. 2 Steps required for soil analysis using LIBS.

methods, and calibration-free models (Takahashi and Thornton, 2017). The second disadvantage is related to the intensity of the lines that can be detected within the spectral range (usually from 200 to 1000 nm) of a conventional LIBS system. Some elements, such as sulfur (S), potassium (P), chlorine (Cl), arsenic (As), lead (Pb), and mercury (Hg), have weak emission lines in this range, and are typically found in soil at trace concentrations. The LIBS LOD can be improved by using (i) appropriate instrument configurations, such as a double-pulse LIBS system, physical plasma confinement, and microwave antenna (Zorov et al., 2015); or (ii) specific sample preparations, such as the addition of nanoparticles (de Giacomo et al., 2016).

Despite these limitations, LIBS has the potential to be used in precision and digital agriculture. In particular, precision agriculture requires the analysis of numerous soil samples, which is time-consuming and costly, especially if conventional methods are used. However, precision agriculture may be made viable with LIBS with its advantages over traditional methods. LIBS can outperform traditional methods even if, individually, the results of the analyses are less precise and accurate than those obtained through conventional methods. This is because the large number of samples in LIBS compensates for possible inaccuracies in the assessment of a soil property. In addition, LIBS can increase the temporal resolution of the sampled area, assisting farmers in managing agricultural lands properly over time. Based on the fertility maps generated, the farmer can add inputs to the soil—such as limestone to correct soil acidity, or fertilizers—at variable rates (Bernardi et al., 2017). Thus, the synergy between precision agriculture and LIBS enables the optimization of agricultural production, lowering costs, and mitigating environmental impacts.

This chapter presents the advantages and limitations of the application of LIBS in soil analysis to quantify plant nutrients, toxic elements, and soil C, in addition to indirectly assessing soil organic matter, pH, base saturation, cation exchange capacity, and texture.

Plant nutrients

The quantification of plant nutrients in soils is crucial for the effective management of a farm because it indicates the optimum amounts of fertilizers to be applied on each field for a crop to maximize productivity, minimize costs, reduce waste, and mitigate environmental impacts. Each plant uses intrinsic mechanisms to extract essential nutrients from the soil, therefore, several methods for plant nutrient analysis have been proposed to measure the bioavailability of these elements. However, methods of plant nutrient extraction vary from country to country, are all time-consuming, require reagents (extractants that mimic the extraction of nutrients from the soil by plant roots), and produce waste, which makes them impractical to implement on a large-scale (including precision agriculture). Therefore, the LIBS technique may be a desirable alternative for quantifying macro- and micro-nutrients in soil samples (Table 1).

Table 1 LIBS limit of detections (LODs) of soil nutrients (as reviewed by Villas-Boas et al., 2020b), compared to CHNS or ICP LODs (according to the manufacturers), and typical content found in soils (Larcher, 2003).

Nutrient (Symbol)	Typical content (mg kg ⁻¹)	CHNS or ICP LOD (mg kg ⁻¹)	LIBS LOD (mg kg ⁻¹)	Most used emission lines (nm)
Macronutrients (primary)				
Nitrogen (N)	2000	100 ^a	8000 ^b	742.36, 744.23, 746.83
Potassium (K)	14,000	50	31	404.72, 518.36, 766.49, 769.90
Phosphorus (P)	800	50	251	178.3, 213.61, 255.32, 255.5
Macronutrients (secondary)				
Calcium (Ca)	15,000	2.5	180	317.9, 318.1, 393.37, 396.8, 428.3
Magnesium (Mg)	5000	2.5	4	280.27, 285.2, 383.23, 383.81, 516.73, 517.26
Sulfur (S)	700	100 ^a	16000 ^c	180.7, 182.1, 182.6, 921.3, 922.8, 923.8
Micronutrients				
Iron (Fe)	40,000	2.5	10	274.6, 274.9, 404.6, 406.4, 407.2, 489.15
Chlorine (Cl)	<100	5 ^d	75 ^e	133.6
Manganese (Mn)	1000	2.5	7	380.67, 403.07, 403.31, 403.45, 475.4, 472.7, 478.3
Boron (B)	20	5	1000	255.14 (BO band)
Zinc (Zn)	90	2.5	7	213.86, 334.50, 334.59, 472.22, 481.05
Copper (Cu)	30	2.5	0.6	282.43, 324.75, 327.4, 510.6, 515.3, 521.8
Molybdenum (Mo)	3	5	0.3	313.26, 550.65

Metallic and metalloid nutrients were measured under ambient air atmospheric conditions, while non-metallic nutrients were measured in a chamber with specific conditions, as indicated in the footnotes.

^aCHNS (CHNS elemental analyzers).

^bChamber with air at 0.04 torr; Ar at 0.3 Mpa; or Ar at 1 atm.

^cChamber with air at 0.02 mbar for VUV; or air at 1 atm for UV-VIS-NIR.

^dICP (inductively coupled plasma—mass spectrometry, ICP-MS), otherwise ICP optical emission spectroscopy (ICP-OES).

^eCO₂ at 7 torr.

Based on Villas-Boas PR, Franco MA, Martin-Neto L, Gollany HT, Milori DMBP (2020b). Applications of laser-induced breakdown spectroscopy for soil characterization, part II: Review of elemental analysis and soil classification. *European Journal of Soil Science* 71: 805–818.

The quantification of metalloid (B, boron) and non-metallic (N(nitrogen), P, S, and Cl) nutrients is difficult with the LIBS technique because the emission lines of these elements are weak in the spectral range (200–1000 nm) commonly used in LIBS systems. For this reason, the LOD for these nutrients is high, and may compromise the analysis of soil samples because the concentrations of some elements, which occur at trace levels in soils, may not be detectable (Table 1). In addition, the LIBS measurement of N, S, and Cl requires a chamber filled with a noble gas (e.g., Ar, argon) or thin (near vacuum) atmospheric air. For the measurement of soil N content, N₂ from the air can contribute to plasma formation, making it impossible to distinguish between N from the air and that from the sample. Sulfur and chloride have strong lines only in the deep ultraviolet range, which requires measurements in a vacuum, and with spectrometers designed for this range (less than 200 nm). Boron also has weak lines in the 200–1000 nm range and can be measured with a boron monoxide (BO) molecular fragment emission band at 255.14 nm (emission of boron oxide (BO) molecular fragment); however, the LOD is much higher than the typical concentration in soils (Table 1).

In contrast to the non-metallic elements, the nutrients potassium (K), calcium (Ca), magnesium (Mg), iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), and molybdenum (Mo) are not difficult to detect with the LIBS technique and can be measured under ambient air atmospheric conditions because they have strong lines within the spectral range commonly used in LIBS systems. Thus, the LIBS LOD for the metallic nutrients is far lower than their typical concentrations in soils (Table 1), which makes the LIBS technique advantageous for these elements. However, the main recommendation for assessing these nutrients is to refrain from using the strongest lines, as they are often self-absorbed and may not bear a linear relation with the concentration of nutrients.

The intensity of a nutrient emission line is correlated with the total concentration of the element in question, therefore, the content of bioavailable nutrients cannot be determined directly with LIBS. To overcome this limitation, multivariate machine learning models can be developed with the LIBS spectra (Tavares et al., 2022), which contain information concerning other elements in the soil sample. Thus, the content of bioavailable nutrients can be obtained through the stoichiometric relation between the elements present in the soil samples, which can be revealed with these models.

In summary, LIBS shows great potential for large-scale analyses of plant nutrients in soils because it is fast, inexpensive, and acceptably accurate. Certain challenges, however, are yet to be overcome, such as matrix effects and the high LOD for non-metallic and metalloid nutrients. Matrix effects can be mitigated with (i) additional sample preparation (e.g., use of a binder, or matrix removal through element extraction methods), (ii) spectral treatment methods (e.g., spectral normalization and wavelet transform), and (iii) physical (calibration-free) or multivariate models (e.g., artificial neural networks). The LOD for non-metallic and metalloid nutrients can be improved with the use of molecular bands, a binder (to enhance emission), double-pulse LIBS systems, or a microwave antenna. For these elements, using a vacuum chamber may still be necessary, especially to ensure the absence of atmospheric N₂ while measuring N content in soil samples.

Toxic elements

For a farm to be managed sustainably and to keep food from becoming contaminated before it reaches the shelves, a quantification of the toxic elements in the soil is critical. Depending on their concentration in the soil, certain elements such as copper (Cu) and zinc (Zn) can be either plant nutrients or toxic. A soil is considered contaminated if the concentrations of certain elements exceed the legal threshold (Table 2), which may vary from country to country. The issue with confirming contamination by these elements in soils is that the method most often used (ICP-OES) is time-consuming, requires reagents for sample digestion, and produces waste, which makes it unviable on a large scale.

The benefits of using LIBS, including its rapid analysis time, affordable cost, and zero waste production, have attracted interest in the technique for the measurement of toxic elements in soil samples. However, traditional LIBS systems are not sensitive enough (i.e., their LODs are high compared to ICP-OES) to detect these elements at the concentrations usually found in soils, i.e., from 1 µg kg⁻¹ to 1 mg kg⁻¹ (Table 2). To reduce the LOD, several strategies were suggested (Zorov et al., 2015), such as (i) using the strong lines (high Einstein coefficient for spontaneous emission) for these elements; (ii) optimizing acquisition of the plasma emission; (iii) increasing the plasma lifetime (e.g., with physical or magnetic confinement, using a microwave antenna); (iv) increasing the plasma's energy (e.g., using double-pulse LIBS systems, electrical discharge coupled LIBS system, laser-induced fluorescence coupled LIBS system); and (v) extracting elements with an acid (phase transformation method). With these strategies LIBS can be performed with far smaller LODs than those of the reference method, except for nickel (Ni) and Zn (Table 2). In principle, the LODs for toxic elements could be further improved by combining various strategies, but that would increase the complexity of the procedure and lengthen the time required for the analysis.

Most studies on toxic elements have focused on improving the LODs, therefore, the issue of matrix effects has not been extensively addressed. In addition, the majority of these studies have used the same type of soil samples, varying only the concentrations of the toxic element of interest, resulting in minor matrix variations among the samples. In real-world situations where agricultural or industrial soil samples are evaluated, matrix effects can compromise quantitative models for these elements. Thus, several methods have been developed to address this problem, including:

Table 2 LIBS limit of detections (LODs) for toxic elements (as reviewed by Villas-Boas et al., 2020b), compared to ICP-OES LODs (according to the manufacturers), threshold values for contamination (according to Finnish Ministry of the Environment, 2007, and based on ecological, groundwater (p), and human health risks), and natural occurrence found in soils (Finnish Ministry of the Environment, 2007).

Element (symbol)	Natural occurrence (mg kg ⁻¹)	Threshold value (mg kg ⁻¹)	ICP-OES LOD (mg kg ⁻¹)	LIBS LOD (mg kg ⁻¹)	Most used emission lines (nm)

Zinc and copper can be either nutrients or toxic, depending on their concentration in the soil. All LIBS measurements were performed under ambient air atmospheric conditions.

Particular measurement conditions are indicated in the footnotes.

^aLIBS assisted with laser-induced fluorescence for Sb emission line.

^bLIBS operating with Nd:YAG laser at 1064 nm, 450 mJ and 5–7 ns per pulse.

^cCoarse metal powder-assisted pulse CO₂ LIBS.

^dLIBS assisted with phase transformation method (solid-liquid-solid).

^eLIBS assisted with laser-induced fluorescence for Co emission lines.

^fLIBS operating with Nd:YAG laser at 355 nm, 21 mJ per pulse.

^gLIBS using hemispherical plasma spatial confinement.

^hLIBS and plasma spatial confinement.

Based on Villas-Boas PR, Franco MA, Martin-Neto L, Gollany HT, Milori DMBP (2020b). Applications of laser-induced breakdown spectroscopy for soil characterization, part II: Review of elemental analysis and soil classification. *European Journal of Soil Science* 71: 805–818.

- A phase transformation method, by which the toxic elements are extracted, which removes the matrix and then the extracts are dried and analyzed with the LIBS technique;
- Spectral normalization, which aims to reduce the variation in intensity of emission lines caused by both laser fluctuation and matrix effects;
- Multivariate models, which employ multiple linear and non-linear relationships between the intensities of the emission lines from various elements (including those in the matrix) and concentrations of the toxic elements of interest;
- Soil classification followed by regression modeling, where a regression model is developed for each soil class;
- Combination of various methods such as normalization, normal data transformation, outlier removal, noise removal, and multivariate modeling.

In recent years, significant advancements have been made in LIBS concerning the quantification of toxic elements in soil samples. However, certain challenges remain to be overcome, such as creating models for several (more than 100) soil samples of differing composition. Furthermore, even for qualitative or semi-quantitative LIBS analyses, in-the-field use of portable systems or systems embedded in field vehicles is still emerging.

Soil carbon

Soil organic matter is of great importance in the biogeochemical carbon cycle because it is the second-largest carbon pool on Earth (Lal, 2004). When properly managed, carbon that is stored as organic matter can improve physicochemical properties of the soil (soil fertility) and, consequently, crop yields. From an environmental perspective, the sequestration of carbon dioxide (CO₂) by plants, and its storage in soil organic matter (preferably with a high degree of humification), can help to mitigate the greenhouse effect, and contribute to an increase in the farmer's profitability through the payment of carbon credits.

Before they can be traded in the recent and thriving carbon market, carbon credits (1 carbon credit = 1 ton of CO₂ equivalent) must be measured by methods that quantify soil organic carbon stock. With that in mind, LIBS has

advantages compared to conventional methods, such as dry combustion and wet acid oxidation (Walkley–Black), when measuring C content in soils. The simplicity, speed, and possibility of in situ analyses are some of the advantages of this technique, in contrast to conventional methods of C quantification. LIBS analysis enables the direct quantification of total C and indirect quantification of organic and inorganic C (using stoichiometric relationships with other elements in the sample). In LIBS, soil samples are prepared as pellets, which eliminates the requirement of (i) tin capsules (used in the dry combustion method) and (ii) oxidizing acids and toxic reagents such as concentrated sulfuric acid (H_2SO_4) and potassium dichromate ($\text{K}_2\text{Cr}_2\text{O}_7$) (used in the Walkley–Black method). Thus, LIBS enables the measurement of soil C to be done more rapidly, at a more affordable cost, and in a way that aligns with the principles of “green chemistry.” The use of LIBS was recently approved by an international certifier (Verra, 2022) for soil carbon credit verification, bringing the technique one step closer to becoming a standard method for routine soil C analyses.

Despite the above benefits, challenges related to spectral interference and matrix effects still need to be overcome in the quantification of soil C in LIBS. The main C emission lines used in LIBS measurements are the atomic lines at 193.03 and 247.86 nm, which are associated with large emission probabilities (Einstein coefficients for spontaneous emission) and high relative intensities. These two lines are observed in conventional LIBS systems and under ambient air atmospheric conditions, although the first is absorbed partially by atmospheric oxygen (O_2). However, aluminum (Al) and Fe lines can interfere with the atomic C lines at 193.03 and 247.86 nm, respectively, which could make the quantification of C in soil samples difficult, especially in tropical soils, e.g., Oxisols. Super high-resolution spectrometers (i.e., resolution of less than 0.01 nm) could be used to overcome the spectral interference observed in the atomic C lines or methods that subtract the Al or Fe contribution from atomic C lines (e.g., Nicolodelli et al., 2014).

A viable strategy to overcome matrix effects is to develop a calibration model for each soil type, e.g., considering textural classes (Segnini et al., 2014). Two calibration models, one for medium-textured soil samples, and another for fine-textured soil samples, were successfully created for total soil C. However, different LODs were obtained for each model because of the texture-related matrix effects. The LOD for the fine-textured soils (0.13% C) was 59% less than that obtained for medium-textured soils (0.32% C).

After these challenges are overcome, LIBS has a great potential for enabling the measurement of C stocks in soils and, consequently, the C credit market. However, the calculation of C stocks in soils also requires soil bulk density, a physical soil property that is labor-intensive and time-consuming to measure. To enable large-scale measurement of soil C stocks, a fast technique other than LIBS that can estimate soil bulk density is required. The next section presents applications of the LIBS technique to assess several soil physicochemical properties, such as texture and pH.

Soil physicochemical properties

In addition to measuring elements, LIBS may also be used to evaluate soil characteristics such as pH, texture (percentages of sand, clay, and silt), cation exchange capacity, base saturation, and the degree of humification of soil organic matter. These properties have been effectively assessed using multielement data from the LIBS emission spectrum, stoichiometric ratios, and multivariate regression models (Table 3).

The soil physical or chemical properties can only be inferred by LIBS from the stoichiometric relationships among the constituent elements of the soil sample, except for total measurements of the elements content (Villas-Boas et al., 2020a). An example is the measurement of soil pH by LIBS (Table 2). This property, which denotes the acid–base balance in soil, can be estimated on the basis of the concentration of elements related to soil acidity or alkalinity (e.g., Al and Ca, respectively). While the former predominates in acidic soils, Ca is associated with soil alkalinity: soil liming is a regular practice to correct soil acidity. The pH of a variety of Brazilian soils was estimated, with an error of 0.4 pH units, from the emission lines of

Table 3 Models (partial least square regression—PLSR, multiple linear regression—MLR, and K-nearest neighbors—KNN), elements or spectral ranges used, and predictive errors—either root mean squared errors (RMSE) or root average errors (RAE)—for assessing soil properties using LIBS.

Soil property	Model	Elements or spectral ranges (nm)	Predictive errors
pH	PLSR ^a	Al, Ca, H, and O ^a	RMSE = 0.40 ^a
	PLSR ^b	220.84–222.21, 237.82–239.27, and 391.78–394.22 ^b	RMSE = 0.33 ^b
Cation exchange capacity	MLR ^b	C, Na, Mg, Al, Si, P, Ca, Ti, Mn, Fe, Cu, and Zn ^b	RMSE = 10.55 mmol _c dm ⁻³ ^b
	PLSR ^c	183–908 ^c	RMSE = 5.4 cmol _c kg ⁻¹ ^c
Texture	PLSR ^a	188–908 or Si, Na, Fe, Ti, Ca, K, Al, Co, Mg, V, Ba, and Be ^a	RMSE = 7% (clay), 8% (sand), 4% (silt) ^a
	PLSR ^b	220.84–222.21, 246.77–248.29, and 251.37–252.94 ^b	RMSE = 27.68 g dm ⁻³ (clay) ^b
Base saturation	PLSR ^b	201.31–272.37, 279.18–300.60 and 396.59–399.10 ^b	RMSE = 5.49% ^b
Humification degree of soil organic matter	K-NN ^a	C, Al, Mg, and Ca ^a	RAE = 33.5% ^a

these two elements and those of hydrogen (H) and O (Ferreira et al., 2015). Thus, to assess any soil property requires multivariate regression models based on the linear and non-linear stoichiometric relationships among the constituent elements in the soil sample.

The simplicity of measurement, speed of analysis, and minimal sample preparation are the key LIBS advantages for these applications compared to conventional methods (Fig. 3). For instance, while traditional methods take at least 2 days to determine soil texture, LIBS analysis requires only a few minutes per sample (Villas-Boas et al., 2016). However, matrix effects can compromise the accuracy of LIBS estimates, in particular when the samples undergoing analysis have a composition that differs significantly from that of the calibration set. To ensure that LIBS is accurate and reliable, it is recommended that a spectral library should be maintained, with the frequent addition of new sample information.

Conclusion

Large-scale agricultural production is necessary to meet the rising global demand for food, which calls for the effective use of agricultural inputs to increase productivity and to mitigate environmental impacts. However, conventional methods of soil analysis are unable to meet these demands because they are costly, time-consuming, require chemical inputs, and produce residues. LIBS presents unique features (rapid analyses, minimal sample preparation, and no generation of residues) that can allow for large-scale soil analyses, as required in precision agriculture. This chapter discussed the key advantages and limitations of LIBS as a method to assess, in soil samples, (i) the total and bioavailable contents of plant nutrients; (ii) the total content of toxic elements; (iii) the total, organic and inorganic C content; and (iv) the physicochemical properties. Despite the limitations, LIBS has great potential to become a standard method for routine soil analyses and to meet the demands of large-scale agricultural production. The use of LIBS

has already been approved by Verra, an international certifier, for soil carbon credit verification, allowing companies to quantify soil C for the carbon market.

Abstract

Calorimetry is the measurement of heat. It has been used since 1780 in Lavoisier and Laplace's ice calorimeter. In environmental soil science, isothermal microcalorimetry, isothermal titration calorimetry, and differential scanning calorimetry provide thermodynamic and kinetic information on various reactions and processes; they are powerful tools to elucidate almost all important topics. There has been an increase in applications of the three typical techniques in determining microbial activity, monitoring the toxicity and biodegradation of organic pollutants, evaluating the risk of metals and metalloids, and investigating the interfacial processes in soils and associated environments. Coupled with other analytical techniques, calorimetry could be promising for research in soil and environmental sciences.

Key points

- Introduction of calorimetric techniques.
- Application of calorimetry in soil science and related fields.
- Recent research advances in calorimetry.

Introduction

In nature, all the physical, chemical, and biological processes are associated with the effect of heat, which is the basis for thermal analysis and calorimetry. According to the International Confederation for Thermal Analysis and Calorimetry, thermal analysis studies the relationship between a sample property and its temperature as the sample is heated or cooled in a controlled manner. There is an overlap in the meaning of the term 'thermal analysis' and 'calorimetry'. In some books or journal papers, they are used indiscriminately or combined. In practice, thermal analysis refers to a group of techniques to study the property of a sample in a controlled temperature program. It is a technique that exists for properties or physical quantities that are measured against temperature. Here the property or physical quantity could be heat, temperature, heat flow, mass, dimension, mechanical, electrical, magnetic, acoustic, and structural characteristics of the sample concerned. Calorimetry measures heat released into or absorbed from the environment during a chemical, physical or biological reaction. Calorimetry focuses on measuring heat changes during a process under particular controlled conditions, such as constant volume or constant temperature. A typical experiment for calorimetric analysis may be designed to measure the heat capacity, enthalpy, entropy, and free energy with high precision and accuracy over a wide range of temperatures controlled by a programmed heating and cooling procedure. Precision and accuracy are the keys for analytical techniques, and also for calorimetric analysis. With the invention of the thermocouple and development of modern electronics, in particular information technology, the variation in temperature and detectable heat effect of a calorimeter could be very small, i.e., the temperature probe can measure to less than one ten-thousandth change of a degree Celsius and maintain the baseline stability at tens of micro-degree Celsius over hours.

Calorimetry is one of the oldest areas of physical chemistry. Lavoisier and Laplace were the pioneers for heat measurement and made the first calorimeter equipment in the world. The application of calorimetry in the environmental area can be traced back to Le Chatelier who determined and compared the dehydration point of several clay minerals (Plante et al., 2009). Since then, thermal analysis and calorimetry have been applied intensively in mineralogy and chemistry. Calorimetry encompasses various processes, including titration, flow, reaction, and sorption (Gaisford et al., 2016). Calorimeters can be classified based on a variety of criteria. It may not be easy to give a consistent classification and provide a clear definition of a group of calorimeters. Sarge et al. (2014) classified calorimeters into three groups: (1) isothermal calorimeters; (2) calorimeters with controlled heat exchange between the

sample and surroundings; and (3) adiabatic calorimeters. Each group can be further classified into subgroups according to practical criteria.

The first commercial calorimeter was produced in the 1950s. There are now tens of calorimetric instruments available. The most recent calorimeter is equipped with a computer to control experimental conditions and automatically collect the experimental data. The technique for measuring tiny quantities of heat and heat power is called microcalorimetry, using a microcalorimeter instrument. Beware that 'micro-' means that the detection limit of the device for heat or heat power can be microjoule or microwatt. Calorimetry has been applied in soil and environmental sciences for a long time. It focuses on the characterization of soil clay minerals, soil organic matter, soil bacterial growth, degradation of organic contaminants, and the interfacial reactions between the solid environmental components and pollutants. The applications of several most commonly used calorimetric techniques, including isothermal microcalorimetry (IMC), isothermal titration calorimetry (ITC), differential scanning calorimetry (DSC) in soil and environmental sciences (Fig. 1), will be introduced in the following sections.

Isothermal microcalorimetry (IMC)

The term 'isothermal microcalorimeter' refers to susceptible calorimetric techniques used in experiments where the temperature remains constant. The sensitivity for such instruments is typically in the range of one microwatt or even better (Wadsö, 2001). The isothermal microcalorimeter is usually designed to work in a static incubation mode. The heat released from the sample ampoules can be real-time monitoring and dynamic analysis of chemical, physical and biological processes for hours, days, even months. Isothermal microcalorimetry is a nonspecific technology. In principle, it can be applied to all types of reactions or processes accompanied by thermal effects. This technique has been employed over a wide range of studies involving life science, material science, and pharmaceutical development over the past years (Yang et al., 2005).

Soil is a complex ecosystem in which many physical, chemical, and biochemical reactions occur. All these reactions are associated with more or less heat release, which can be monitored conveniently by microcalorimetry. Isothermal microcalorimetry is a powerful tool for investigating these processes because their thermal effects depend only on the system's initial and final energy states regardless of the types of reactions and stages of the processes.

Determination of soil microbial activity and biomass

Microorganisms are the most active organic components in soils. The interactions between microorganisms and other soil constituents profoundly affect the physicochemical and biological properties of the soil ecosystem. Microorganisms are also responsible for various biochemical reactions during the evolution and formation of soils. These reactions and processes that occur as a result of microbial activity generate a flow of heat which is easily monitored with a microcalorimeter by putting a small amount of soil into the incubation ampoules. The bacterial heat release of the soil versus growth time collected by microcalorimeter interestingly shows a pattern similar to the bacterial growth curve, including a latency phase, a logarithmic phase, a steady phase, and a dead phase (Barros and Feijóo, 2003). The growth rate constant and the metabolic enthalpy can also be determined by calculating the heat evolved due to microbial metabolism in the soil (Núñez-Regueira et al., 2006). By changing the incubation condition in the ampoules, such as moisture, organic matter content, plant nutrient, and the incubation temperature, much information related to soil microbial activity and soil health can be acquired. It has been demonstrated that both total soil heat

Fig. 1 Applications of calorimetric analysis in soil and environmental science.

production and the microbial growth rate constant are strongly correlated with soil moisture, and soils with a larger organic matter content generated more heat (Barros et al. 1997).

The metabolic enthalpy change (ΔH_{met}) of soil microorganisms can be calculated using the microcalorimetric method. The ΔH_{met} reflected the competition among the microorganisms, providing valuable information on the interactions among microbial populations. Microcalorimetry is a highly sensitive method to assess the overall soil microbial biomass. The soil microbial biomass C determined by microcalorimetry was strongly correlated with that measured by O_2 consumption (Raubuch and Beese, 1999). The data on microbial biomass C obtained using the chloroform fumigation method did not reflect the interactive effect on active soil microbiota. However, the data from microcalorimetry provided information not only on soil microbial activity but also on the competition among microbial populations and the inhibitory effect of metabolites (Barros et al., 2000). Traditional techniques, such as fumigation determine the biomass, corroborating the validity of the microcalorimetric method in assessing soil microbial activity and biomass. Ahamadou et al. (2009) proposed that the peak height (P_{max}) and peak time (t_{max}) obtained from the thermograms could be used as good indices of soil microbial activity. In addition, these calorimetric parameters, P_{max} , t_{max} , total heat evolution (Q), quantitatively reflect the influence of organic matter and water gradients on microbial activity (Hassan et al., 2014).

Bacteria and minerals are the essential components of soil. However, the interactions between bacteria and minerals have received scant attention. By monitoring the thermograms of bacterial growth by IMC, Rong et al. (2007) reported that kaolinite, montmorillonite, and goethite stimulated the exponential growth of *Bacillus thuringiensis*, whereas the sporulation growth of *B. thuringiensis* was somewhat inhibited by kaolinite and montmorillonite (Fig. 2). Goethite significantly depressed the sporulation and the total metabolic activity of the bacterium. Wu et al. (2014) also examined the effects of soil colloids and minerals on the metabolic activity of *Pseudomonas putida* by microcalorimetry. They found that montmorillonite markedly improved the metabolic activity of *P. putida*, whereas kaolinite, goethite, and soil colloids significantly inhibited the activity. In calorimetric monitoring of

Fig. 2 Isothermal titration calorimeter (A: TAMIII instrument, B: titration unit; C: electrical system; D: single titration channel).

the biodegradation of methyl parathion in the presence of minerals, Zhao et al. (2014) found that kaolinite enhanced the biodegradation of parathion by stimulating bacterial activity. The calorimetric method provides different and complementary information to that from other techniques in characterizing microbial activities.

Monitoring the toxicity and decomposition of soil pollutants

Understanding the behavior and fate of anthropogenic xenobiotics released into the environment always attracts the attention of environmental scientists. The toxicity and rate of biodegradation of xenobiotics can be readily assessed using microcalorimetry. The microbial activity may be disturbed by xenobiotics and shows a unique heat release signature. For example, the growth of *Tetrahymena pyriformis* was progressively inhibited as the concentration of diuron increased, revealing that the state of the living system was severely altered at a concentration of $56.0 \mu\text{g mL}^{-1}$ (Bricheux et al., 2013). The IC_{50} (half-maximal inhibition concentration) was also estimated at $13.8 \mu\text{g mL}^{-1}$ by microcalorimetry. Calorimetry is a noninvasive technique. The toxicity estimates can be derived directly from the physical response of a living system. Sachs et al. (2017) demonstrated the concentration-dependent influence of U(VI) on the cell metabolism of *Brassica napus*, a plant known to be able to accumulate heavy metals. These studies showed that microcalorimetry is an effective tool for determining the growth rate constant and for rapidly detecting metabolic perturbations.

In a study on the decomposition of pesticide 2,4-dichlorophenoxyacetic acid (2,4-D) using the microcalorimetry method, microbial activity was inhibited by heavy loads of 2,4-D in soils (Prado and Airolidi, 2002). The influence of diuron on soil microbial activity indicated that the original thermal effect gradually decreased with increasing amounts of diuron in soil from 0 to $333.3 \mu\text{g g}^{-1}$. Soil microbial activity decreased by 87.4% in the presence of $10.00 \mu\text{g g}^{-1}$ free picloram. In contrast, a decrease of 54.6% was detected for the same amount of immobilized picloram, suggesting that free picloram was more toxic than immobilized picloram. Likewise, Critter and Airolidi (2001) observed significant influences of different pesticides on soil microbial activities by microcalorimetry. They found that increasing amounts of these pesticides in the soil decreased the exothermal effect from 2234 to 1987 kJ mol^{-1} for paraquat, 1670 to 1306 kJ mol^{-1} for diquat, and to a greater extent from 2239 to 589 kJ mol^{-1} for phosphamidon. Huang et al. (2009) found that the catalytic enthalpy of free phosphatase was greater than that of immobilized phosphatase on montmorillonite and soil colloids, indicating that enzymatic activities were inhibited by immobilization.

Heavy metals and metalloids are hazardous to the environment and human health. Based on heat evolution from intact cells, McGuinness and Barisas (1991) developed a bioassay for the acute toxicity of heavy metals including Hg (mercury), Cd (cadmium), Cu (copper), Pb (lead), Cr (chromium), V (vanadium), and As (arsenic). The EC_{50} of heavy metals obtained from heat production of *Photobacterium phosphoreum* agreed with the results obtained using chemiluminescent assay. The reduction in heat output from cells reflects the inhibition of cell metabolic processes by toxicants, which is a better predictor of biotoxicity than chemiluminescence because that heat production is directly related to the overall metabolism. The influences of metals or metalloids on the heat effect of microbial metabolism depend on the types and concentrations of metals or metalloids. Low concentrations of heavy metals normally stimulate the metabolic heat production of *Rhizopus nigricans*, whereas large concentrations of heavy metals depress heat production. On the basis of the microcalorimetric study, the toxicity of four metals on *R. nigricans* was of the order of $\text{Cd}^{2+} > \text{Hg}^{2+} > \text{Pb}^{2+} > \text{Cu}^{2+}$, and the IC_{50} of these heavy metals was 0.8, 1.7, 48.0, and $110 \mu\text{g mL}^{-1}$, respectively. The heat generation of *T. thermophila* was stimulated by $0.2\text{--}0.4 \text{ mg L}^{-1} \text{ Cu}^{2+}$ or $5\text{--}10 \text{ mg L}^{-1} \text{ Cd}^{2+}$. Toxicity of the two-metal system was greater than that of the one-metal system. For example, the growth of *Bacillus thuringiensis* was enhanced by low concentrations of Cu^{2+} ($5\text{--}30 \text{ mg mL}^{-1}$), possibly because Cu^{2+} ions ensured that the cells had an appropriate flow quality and enabled the synthesis of DNA and RNA. The heat output was suppressed entirely by 20 nmol mg^{-1} of Hg^{2+} due to its inhibitory effect on the phosphorylation of the mitochondria (Zhu et al., 2006). The lag phase in the power-time curve of the sulfate-reducing bacteria, *Desulfomicrobium norvegicum* and *Desulfovibrio vulgaris*, was prolonged in the presence of chromium (VI) (Chardin et al., 2002). The greater the concentration of chromium, the longer was the lag phase. Microcalorimetric study on bacterial metabolism affected by heavy metals has been regarded an appropriate method for screening chromium-resistant bacterial strains, which is of help in the bioremediation of chromium-polluted soils. Airolidi and Critter (1996) showed that the thermal effect of Latosol decreased after the addition of copper sulfate. Heat production reached zero when the amount of copper sulfate increased to 6.19 mg in 1.5 g soil, suggesting that CuSO_4 significantly inhibited the activity of soil microorganisms. A kinetic equation describing the biodegradation mechanism of glucose influenced by CuSO_4 was then fitted based on the calorimetric data. The quantitative thermal information of soils could be used to understand better the influence of heavy metals on various environmental ecosystems.

Isothermal titration calorimetry (ITC)

The isothermal microcalorimeter designed to work in titration mode is called the isothermal titration calorimeter (Fig. 2), in which one of the reaction components (titrant) is injected/titrated into a vessel filled with the other components (titrand) maintained at a constant temperature. In an isothermal titration calorimeter, the addition of titrant into the reaction vessel can be done in one single titration or be added in stepwise increments. A stirrer controlled by a computer ensures thorough mixing. The heat generated or consumed in the reaction vessel is compensated for by the Peltier pile. Both reaction kinetics and thermodynamic parameters, such as enthalpy change (ΔH), Gibbs free energy change (ΔG), entropy change (ΔE), and reaction stoichiometry, can be easily obtained from the power-time curves of the ITC experiment. Because titration microcalorimetry provides information on binding enthalpy

Fig. 3 The power–time curves for the titration of bacterial suspension into clay mineral systems (A, kaolinite, 25 °C; B, montmorillonite, 25 °C; C, kaolinite, 40 °C; D, montmorillonite, 40 °C) (Rong et al. 2007).

change and binding constant, it has been used in studies on specific fast reactions such as enzyme kinetics and the ligand-binding process, which requires minutes or hours to proceed to completion (Hong et al., 2021) (Fig. 3).

The ITC has been used to measure surface reactions in the soil, such as adsorption of heavy metals, cation exchange, phosphate sorption, biomolecules adsorption on soil particles, and mineral–microorganism interfacial reactions. For instance, Cd^{2+} adsorption on goethite was an exothermic process, and the heat release in adsorption was correlated with the equilibrium concentration of Cd^{2+} . The specific adsorption of Pb was predominantly driven by a change in entropy since there was no detectable heat associated with this reaction in a Ultisol and an Oxisol (Appel et al. 2002). The adsorption of Ca and Pb, when replacing exchangeable K, was endothermic. The heat exchanged was less for Pb than for Ca in both soils, indicating that more energy was required for Ca^{2+} than for Pb^{2+} to replace K^+ from surfaces of soil particles. In the Oxisol, there was no change in the amount of heat needed to replace the remaining K^+ as divalent cation saturation increased, suggesting that the exchange sites were energetically similar in this soil. However, a more significant amount of energy was required to remove K^+ as the amount of exchangeable K decreased in the Ultisol. Rhue et al. (2002) found that Na^+ ions experienced considerable difficulty in replacing exchangeable K^+ ions from the Ultisol containing an expanding 2:1 layer silicate clay. The reaction of phosphate with the Ultisol and amorphous $\text{Al}(\text{OH})_3$ was exothermic. Precipitation of Al-phosphate was shown to be endothermic, confirming that precipitation was not the primary mechanism for phosphate sorption. Cai et al. (2006) reported that the adsorption enthalpies of DNA on permanent-charge soil colloids were higher than those on variable-charge soil colloids, and DNA adsorption on organic clays was endothermic, whereas that on inorganic clays was exothermic. Similar results also showed that DNA adsorption on pure montmorillonite was an endothermic reaction and that on hydroxyl aluminum-coated montmorillonite it was exothermic (Cai et al., 2008). The ITC is a convenient method to study adsorption in a complex system, such as the bacteria–mineral composites in soil. The titration of Cu^{2+} solution into bacterial, mineral, and bacteria–mineral composite suspensions and found that Cu^{2+} adsorption on bacteria releases more heat than those of mineral and bacteria–mineral composites. In the montmorillonite- and goethite–bacteria composite systems, ITC verified that the adsorption of Cd, Cu and Pb did not conform to component additivity, and site masking models were proposed to predict the binding and distribution of heavy metals on multi-component soil interfaces, especially at large concentrations of metal ions and large contents of microbial biomass (Qu et al. 2018, Fig. 4).

The adhesion between bacterial cells and soil minerals can also be monitored by ITC. Hong et al. (2011) presented some earlier research about the adsorption of *Bacillus subtilis* on three clay minerals which was an exothermic processes, with enthalpy changes ranging from -52 to 141 kJ kg^{-1} . By further analysis of the dependence of adsorption enthalpy on temperature, pH, and salt concentration, they concluded that electrostatic attraction might play a critical role in bacterial adsorption on clay minerals. Chen et al. (2016) revealed that the entropy increases of excluded water rearrangement and dehydration play key roles in the interaction between DNA and *P. putida*-montmorillonite/goethite composites. Recently, Hong et al. (2021) reported that the negative change in enthalpy was mainly assigned to the ligand exchange of phosphate adsorption on four soil colloids in the pH range from 5.0 to 8.5.

Fig. 4 The power-time curves (A) and the cumulative heat (B) for Pb titration to montmorillonite in the presence of 0.01 or 0.1M NaNO_3 at initial pH 4, 5 and 6. Solid curves represent model prediction (Qu et al. 2018).

The ITC could discriminate between the interactions of proteins and silver nanowires. The negative entropy and negative enthalpy changes of lysozyme adsorption on the silver nanowires might arise from conformational restriction and electrostatic interaction, while the bovine serum albumin and ovalbumin have very weak interaction with the nanowire with ITC detecting minimal adsorption energy.

Differential scanning calorimetry

Differential scanning calorimetry (DSC) measures the energy introduced to a system as a function of temperature. The instrument may work in two modes, heat-flux or power compensation, depending on the method of measurement used. In the heat-flux DSC,

the instrument directly determines the difference in temperature and rate of heat flow between the sample and reference. In a power compensation DSC, the power supplied is varied to compensate for deviations in temperature to establish a near-zero temperature difference between the sample and reference. The DSC is a powerful tool that is used extensively in determining the stability of biopolymers and biological membrane structures in the life sciences, molecular recognition and stability of drugs, protein denaturation, and the order–disorder transition of protein and starch in food science, and the phase transition in material science.

Differential scanning calorimetry has become increasingly popular in the characterization of soil organic matter, clay minerals, and pollutants in soil and the environmental sciences. Wang et al. (2019) systematically evaluated the effects of clay and organic matter content on soil specific heat capacity. They found that organic matter and tightly bound water are the keys for specific heat capacity, and that fine-textured soils possess a larger specific heat capacity than coarse-textured soils. Microplastics are manufactured as microbeads, capsules, fibers, or pellets with a particle size of less than 5 mm. They are widely distributed in all environmental compartments and have attracted increasing attention worldwide. The branching, impurity, additives, and sample size of microplastic polymer affected its phase transition temperatures obtained by DSC. With DSC, Tang et al. (2020) proved that aged plastic lost 12% of its crystallinity compared to that in a pristine state. Differential scanning calorimetry is usually linked with other thermal techniques, for example, thermal gravity analysis (TGA), differential thermal analysis (DTA), and microcalorimetry, or coupled with spectroscopy, microscopy, and chromatography. Dell'Abate et al., (2003) investigated the thermal behavior of humic substances extracted from temperate and tropical soils by DSC/TG coupled with mass spectrometry. The thermal recalcitrance and decomposability of the organic materials were valuable indices for the stability of humic substances.

Conclusions

Calorimetric analysis enables the continuous monitoring of samples for a prolonged period. The samples collected from the different environmental compartments can be used for calorimetric analysis as received with no need for pretreatment before loading into a calorimeter, which maintains the sample in its original form rather than destroying its structure. This is a significant advantage of thermal analysis and calorimetry over chromatography, mass spectrometry, and other techniques that need thorough and laborious sample preparation. Soil and environmental scientists have been applying the three typical calorimetric analysis techniques, IMC, ITC, and DSC in their research. These techniques offer not only new insights into the reactions and processes in soils and associated environments, such as the thermodynamic mechanisms involved in the adsorption and desorption of organic molecules, inorganic ions, and pollutants on soil particles, but also facilitate further understanding of the thermodynamics and kinetics of enzymatic reactions in the soil system.

It is expected that thermal analysis and calorimetry will be used more extensively in the field of soil and environmental science in the future. In particular, the combination of calorimetry with other techniques would help to provide an integrated understanding of the various processes related to soil health, soil pollution and remediation, soil ecology, and global change.

Abstract

Nano-scale secondary ion mass spectrometry (NanoSIMS) offers an unprecedented tool to complement classical quantitative measurements (e.g., isotopic ratio, elemental composition) by high resolution imaging of isotope and elemental distributions. It represents a unique technique to follow isotopically labelled compounds at soil microscale hot spots. Intact soil structures can be studied and their individual associated components like microaggregates, iron (hydr)oxides, bacteria, particulate organic matter surfaces or macroaggregate and soil core sections at the relevant process scale with a resolution to ~ 100 nm. The chapter includes the technical basics, a short introduction to sample preparation, and several exemplary studies to illustrate NanoSIMS.

Key points

- Introduction to the principle of secondary ion mass spectrometry.
- Requirements for properties and preparation of soil samples for successful NanoSIMS measurements.
- Need to accompany NanoSIMS measurements by multiple imaging techniques to yield a more complete understanding of microscale soil processes.
- Approaches for the analysis of soil mineral surfaces with a special emphasize on organo-mineral associated organic matter.
- Approaches to study soil processes in intact soil structures, ranging from aggregates to larger intact soil structures like rhizosphere or soil core sections.
- Applications for using NanoSIMS in soil microbiology.

Introduction

The need for techniques that allow the study of soils at the process scale

Soils comprise a highly complex three-dimensional system in which biological, chemical and physical processes are intricately connected. Most of the mechanisms and processes that determine soil functions like carbon storage, fate of pollutants or nutrient cycling take place at nm (nanometer) to μm (micrometer) scales, but have implications at much larger scales. Thus, allocation of plant-derived organic matter (OM) takes place at the interfaces between plant litter, roots, microorganisms and soil, but has implications for large scale organic carbon (OC) storage and greenhouse gas emissions (Hallett et al., 2013). Mineral soil structures and their reactive surfaces range from nm and μm scales such as clay minerals and Fe/Al (hydr)oxides (Patzner et al., 2020) to larger structures of several μm for micro- and macro-aggregates which are hot spots for the occlusion of particulate OM and regulate the persistence of OC in soils (Witzgall et al., 2021). The exploration of very fine structures in soils and the functional association of its microscale entities dates back to the early 20th century and was refined using electron microscopy later in the same century (Mueller et al., 2013). The study of soils at the microscale for long remained rather descriptive and based on deriving functions and processes from specific soil structures. Over the last two decades, the rapid increase in the technical capability and accessibility of spectro-microscopic techniques, now allow structural information to be combined with chemical composition as well as elemental and

isotopic information (Mueller et al., 2013). An interesting tool to unravel soil microscale processes is nano-scale secondary ion mass spectrometer (NanoSIMS) due to its ability to image stable isotopes at an unprecedented spatial resolution. Starting in the 1990s with the development of the technique and the first attempts to use NanoSIMS in soil research in the early 2000s (Herrmann et al., 2007), it is now an approach that is easier to access with the increase in available laboratories and the further development of suitable experimental settings, sample preparation, and modern image classification tools. This chapter summarizes the technical principle of secondary ion mass spectrometry as a prerequisite to understand the specific requirements for sample preparation and the measurement itself. The application of NanoSIMS in soil science will be illustrated starting with the specific use to unravel the microspatial organization of organo-mineral interfaces and microscale soil structures (e.g., microaggregates), followed by plant-soil interactions, and its application in soil microbiology.

The technical principle of NanoSIMS

SIMS

Secondary ion mass spectrometry (SIMS), successfully used in environmental research, is becoming a central tool to resolve spatially the elemental composition of solid soil samples (Lamberti, 2005). An energetic ion beam (hundreds of eV to tenth of keV, e.g., O^- (oxygen), Cs^+ (cesium), Ga^+ (gallium)) is accelerated onto a sample under high vacuum conditions (10^{-8} – 10^{-10} Torr in the analysis chamber) inducing a collision cascade by kinetic energy transfer. This leads to the ejection of secondary species (ions, neutrals, electrons, atoms, clusters) from the sample surface, a process called sputtering. According to the ion dose impacting the sample, SIMS can be static (below the static limit of 10^{13} ions cm^{-2}), with no chemical damage of the sample, or dynamic, when the sample is actively eroded after the primary dose has overcome the static limit (Walker, 2010). The particles escaping the surface in an ionized state, the so-called secondary ions, are accelerated into a mass analyzer where they are differentially recorded according to their mass/charge ratio (Fig. 1). The power of the SIMS technique is the detection of elements as well as stable isotopes with a very high sensitivity in the ppm range. There are three types of mass analyzers commonly used in SIMS: time-of-flight (TOF), quadrupole, and magnetic sector analyzers, each having advantages and disadvantages (Walker, 2010). The TOF instruments are preferred for static SIMS and molecular depth profiling, quadrupole and magnetic sectors are used for dynamic depth profiling, while magnetic sector instruments are widely used in studies that require a high mass resolving power. Although, SIMS is a qualitative technique due to the different ionization potential of elements, semi-quantitative analyzes are possible by comparison to standards with known concentrations or isotopic signatures.

NanoSIMS

In the late 1990s, a new design of a dynamic SIMS instrument revolutionized the research community (Hillion et al., 1994). Using a unique co-axial configuration (see Fig. 1), Cameca Gennevilliers, France developed the so called NanoSIMS 50/50 L instrument capable of performing SIMS analyzes at an unprecedented submicron spatial resolution and high transmission (Mueller et al., 2013 and references within). The instrument is equipped with two exchangeable sources of reactive ions (Cs^+ and O^-), delivering a beam that can be focused to the nanometer scale. Lately, a new RF (radio frequency) O^- plasma source with an improved spatial resolution (~ 50 nm) was developed to replace the previous duoplasmatron (~ 200 nm lateral resolution). This enables the same spatial resolution to be achieved for positively (using O^- source) and negatively (using Cs^+ source) charged secondary ions (see Fig. 1). Presently, up to 7 masses (50 L configuration, 5 for the NanoSIMS 50) can be measured simultaneously at a lateral resolution down to 50 nm in both polarities.

The secondary ions escaping the sample surface are directed into the detection system consisting of a double focusing magnetic sector. This enables the accurate separation of isobars at the same mass number, resulting in a high mass resolving power (MRP) of $>10,000$ provided by the NanoSIMS instrument. A high mass resolution is crucial to measure ion species accurately, especially when experimenting with stable isotope labeling (^{13}C (carbon-13), ^{15}N (nitrogen-15), ^{18}O (oxygen-18), ^{29}Si (silica-29), ^{44}Ca (calcium-44)). In 'imaging mode' secondary ion species can be registered at high lateral resolution using electron multipliers (EMs, 6 movable and 1 fixed) or in the so called 'spot mode' counted using Faraday cups (FCs), with a better precision in the per mill range (no imaging in this case). By scanning the focused primary ion beam with a defined number of steps (pixels, e.g., 256×256), a fixed dwell time for each pixel (e.g., 1 ms $pixel^{-1}$), and an appropriate field of view (e.g., $25 \mu m \times 25 \mu m$) over the sample, the elemental distribution is visualized by the detected secondary ions. In general, these parameters are chosen so that the size of a pixel is smaller than the size of the primary beam to avoid over-measuring. Multiple cycles can be registered to reach better ion statistics by accumulating all counts on every single pixel, for example stacking single image layers to form an accumulated image. There are several software packages for analyzing the acquired data. Some of them are under license, such as L'Image developed by L. R. Nittler, Carnegie Institution of Washington and WinImage developed by Cameca accompanying the NanoSIMS instrument. Other software packages have been developed by users and are open source (Look@NanoSIMS developed by L. Polerecky and the OpenMIMS plugin of the Fiji-ImageJ interface) (Polerecky et al., 2012). According to the needs, the user can choose the most suitable one. In general, all of these software packages enable the first processing steps, consisting of dead time correction of the ion signal measured on the electron multipliers and drift correction of the multiple planes and their accumulation. Furthermore, isotopic/elemental ratios can be calculated.

The unique capabilities of NanoSIMS for image isotopic enrichment at a submicron lateral resolution have resulted in many applications in multidisciplinary research fields. Moreover, apart from applications in fields such as materials science, geosciences,

Fig. 1 Schematic diagram illustrating the technical background of the NanoSIMS technique from the sample holder, sample surface and coaxial setup in (A) to the final images in (B). (A) On the left a sample holder and two ways of mounting samples (embedded cross section and fine particles on Si-wafer) are displayed. The close up shows the sputtering process with primary ions (red arrows), and extracted secondary ions (green arrows). The coaxial setup of the NanoSIMS with primary ion beam (in red) and secondary ion beam (in green) in one plane enables the high spatial resolution of the instrument. This setup requires that secondary and primary ions have the opposite charge to enable the extraction of the ions to the spectrometer. In (B) final images are displayed from a fine grain soil sample measured with Cs⁺ and with O⁻ as primary ion, which yields negative and positive secondary ions, respectively.

cosmochemistry, microbiology, or medical science (Hatton et al., 2012; Hoppe et al., 2013; Musat et al., 2016; Pett-Ridge and Weber, 2021), NanoSIMS has revolutionized the field of soil science (Herrmann et al., 2007; Keiluweit et al., 2012; Remusat et al., 2012). It is an important advance in technology that enables us to identify the arrangement of soil constituents and gain insight into their interactions at the sub-micrometer scale, matters which have hitherto been impossible.

Requirements for samples before and during measurement

The successful utilization of SIMS for surface analyzes is determined by a variety of factors. There are universal factors which apply to all SIMS instruments and concern the sample characteristics: only samples that are stable under high vacuum conditions can be measured. Furthermore, as little as possible topographical unevenness is recommended as it strongly influences the quality of the results. It is preferable to have conductive samples, but samples can be measured after coating with a thin conductive layer (e.g., carbon, gold), which does not interfere with the species of interest. Additionally, some systems allow the measurement of isolated samples via charge compensation, e.g., by flooding the sample with electrons. It is worth noting that adjustment of the neutralization system is always challenging.

The application of isotopic labels is a widely used approach to unravel allocation and transformation of elements and organic compounds in soil microenvironments. NanoSIMS offers a wide range of detectable isotopes, therefore, one is not restricted to the most commonly used ¹³C and ¹⁵N to trace organic matter transformation or microbial activity, but may also use ¹⁸O for instance to

trace soil phosphorus as $^{31}\text{P}^{18}\text{O}$ or ^{57}Fe to study iron oxide formation. Thus, NanoSIMS can support classical quantitative isotopic ratio mass spectrometer data with high resolution imaging of the reactive sites and interfaces involved in the targeted processes.

It is important that the investigator carefully plans the experiment before starting the sample preparation and measurement campaign. When the aim is to reveal processes by identifying the location of isotopic enrichment by stable isotope labeling, which is used in many environmental sciences and intensively so in soil research, decisions must be taken on the pre-treatments: which substances, labeling isotopes, and enrichment are involved, and in what way and time scale is the experiment performed.

Once these parameters are fixed, a procedure for sample preparation for the final NanoSIMS measurements should be specified. It has to be considered that the sample holder has an upright position in the measuring chamber, so the sample must be well fixed. For soil science, from experience two ways have been established for working with fine sized particles (e.g., microaggregates, clay minerals) either on flat wafers (e.g., Si wafer) or filters or with embedded cross sections of intact soil samples. Both of these techniques have advantages and disadvantages, and the decision is mostly made based on the research question and the size of sample.

Small particles (fine silt- and or clay-sized particles not exceeding 20 μm in overall sample topography) are commonly deposited on a flat substrate that fits the SIMS sample holder (e.g., Si or GaAs wafers). This method has the advantage that the sample is not in contact with any embedding material (e.g., epoxy resin). A drawback, however, is that the topography of the particles induces possible edge artifacts and they might move in water solution. To reduce the latter, we currently use cold-substrate fixation making use of condensation rather than exposing the whole sample to water in a suspension. A wafer is cooled well before depositing particles on it by sieving, thus taking advantage of the condensation of air humidity to fix small soil particles onto the sample holder's substrate (e.g., Si wafer). In rare cases it is also possible to work directly on sample surfaces if they resemble larger flat areas such as on particulate organic matter (Witzgall et al., 2021).

The topographical drawback of small particles can be overcome by embedding them. Applying a sufficiently thick coating onto the particles' surface before embedding allows the particles' carbon species to be separated from the embedding resin, as reported by Hoeschen et al. (2015).

For structures $>20\ \mu\text{m}$ (soil aggregates, intact plant-soil systems like the rhizosphere), embedding with epoxy or polyester resins is a well-established method. However, care has to be taken that a high vacuum stable resin is used. Araldite 502 has been successfully used due to its low N content, resulting in a good contrast of the C/N ratio of this resin and SOM (Herrmann et al., 2007). It was possible to separate the Araldite epoxy NanoSIMS signal from the SOM ion signal by appropriate supervised and unsupervised image classification (Steffens et al., 2017). The embedded samples are polished as flat thin sections; they are favored over thick blocks due to a rapid outgassing before loading them into the analyzes chamber. Applications in which samples need to be embedded are gradient investigations at biogeochemical interfaces of intact larger samples (e.g., intact soil macroaggregates as in Fig. 2). This is of particular interest, for example, at the root-soil interface where exchange processes of nutrients are very intensive. As an alternative to resins, embedding in molten sulfur and cryofixation were also applied for preparing cross sections of structures $<100\ \mu\text{m}$ with the advantage of avoiding carbon contamination (Lehmann et al., 2005), but due to the rather complex preparation this approach is not widely used. Sectioning of samples with focused ion beam (FIB), usually used to produce thin sections for subsequent analysis by transmission electron microscopy, looks promising, but requires specialized equipment and only a limited volume of a sample can be processed (Vidal et al., 2018).

A single NanoSIMS measurement depicts only a very small field of view and the measurement time is costly, therefore, an important preliminary step before NanoSIMS analysis is a detailed imaging cascade of the whole sample to identify representative regions of interest (ROI). We recommend an intense investigation starting with optical microscopy, with areas of greater interest being imaged at the highest possible magnification. This step can also include staining of, for example, microorganisms to locate interesting 'hot spots' of microbial activity and or combine the imaging with phylogenetic information using fluorescent in situ hybridization (FISH) (Musat et al., 2016; Schlueter et al., 2019). Alternatively or additionally, a secondary electron microscopy (SEM) screening can be beneficial to obtain highly resolved images of ROIs. For embedded soil sections with low topographic contrast use of the backscattered electrons (BSE) detector of the SEM allows details based on elemental contrasts to be revealed. In addition, correlative imaging (e.g., helium ion microscopy, fluorescence microscopy, confocal microscopy, atomic force microscopy) are advised to target research-specific parameters and add value to the NanoSIMS analyzes (Mueller et al., 2013 and references within). To co-locate positions between all imaging methods, a coordinate transformation can be applied. Therefore, at least two distinct reference spots (unique pattern, sample edges, scratches, indications marked onto sample using laser) are referenced in each method's coordinate system.

The revolutionary coaxial configuration of NanoSIMS enables very high lateral resolution and high transmission, therefore, there is a constraint on the polarity of the primary ions sputtering the sample and the secondary ions leaving the sample surface: their charge has to be opposite. As chemical elements present different electron affinities and ionization potentials, this requires an early decision on which ion source needs to be used. For soil samples, there are two phases of interest, organic matter (OM) and mineral constituents. To depict the spatial distribution of OM, the key elements carbon and nitrogen are targeted as the species ^{12}C and ^{14}N . As carbon ionizes predominantly negatively and only poorly positively, the $^{12}\text{C}^-$ secondary ions leaving the sample need to be detected. This requires use of the Cs source to provide positive primary ions. In this configuration, nitrogen is detected as $^{12}\text{C}^{14}\text{N}^-$ (the elemental ionization of nitrogen is very poor, neither negative nor positive), while the ^{13}C (as $^{13}\text{C}^-$) and ^{15}N (as $^{12}\text{C}^{15}\text{N}^-$) stable isotopes can be measured simultaneously. The measurement of further OM-specific elements, such as phosphorus (^{31}P) and sulfur (^{32}S), and specific mineral elements (^{28}Si , $^{27}\text{Al}^{16}\text{O}^-$, $^{56}\text{Fe}^{16}\text{O}^-$) is possible. A typical configuration to cover OM and mineral compartments in soil samples treated with isotopic labels would be: $^{12}\text{C}^-$, $^{13}\text{C}^-$, $^{16}\text{O}^-$, $^{12}\text{C}^{14}\text{N}^-$, $^{12}\text{C}^{15}\text{N}^-$, $^{27}\text{Al}^{16}\text{O}^-$,

Fig. 2 A polished cross section of an embedded soil macroaggregate analyzed by Steffens et al. (2017) along a regular grid using NanoSIMS. The reflected light microscope image indicates the 40 NanoSIMS measurement locations (yellow blocks). On the left, images from a scanning electron microscope (SEM) and the NanoSIMS data for three locations are shown that represent distinct functional microdomains. All SEM and NanoSIMS images are $30\ \mu\text{m} \times 30\ \mu\text{m}$ in size. Reprinted with permission from Steffens M, Rogge DM, Mueller CW, Höschen C, Lugmeier J, Kölbl A and Kögel-Knabner I (2017) Identification of distinct functional microstructural domains controlling C storage in soil. *Environmental Science & Technology* **51**(21): 12182–12189, Copyright (Steffens et al., 2017) American Chemical Society.

$^{56}\text{Fe}^{16}\text{O}^-$. Other species such as magnesium ($^{24}\text{Mg}^+$), calcium ($^{40}\text{Ca}^+$), or potassium ($^{39}\text{K}^+$) need to be measured as positive ions ($^{24}\text{Mg}^+$, $^{40}\text{Ca}^+$, $^{39}\text{K}^+$), using the O^- source of the instrument. This configuration also allows the successful measurement of silicon, aluminum, and iron ($^{28}\text{Si}^+$, $^{27}\text{Al}^+$, $^{56}\text{Fe}^+$).

Once the sample has been well documented and the decision made of which primary ion to use, the sample is ready for loading into the NanoSIMS load lock. Soil samples tend to have charging issues on the isolating minerals (e.g., quartz grains), therefore, a thin coating (10–30 nm) with a gold-based alloy is applied independently of preparation and sample size.

According to the size of the sample, different standard sample holders can be chosen that fit into the NanoSIMS stage system with different configurations. A standard sample holder can store multiple samples with a diameter of 10 mm. For investigations of isotopic enrichment, we recommend analyzing control samples loaded on the same holder of natural isotopic abundance in the same session. Other typical sample sizes have diameters of 5 mm, 12.5 mm, or 25.4 mm.

The machine has to be carefully tuned (Mueller et al., 2013 and references within) at the outset, setting an appropriate mass resolution to detect masses affected by isobars accurately (e.g., at mass number 13 when measuring ^{13}C , which interferes with $^{12}\text{C}^1\text{H}$). The first tuning for a new sample series can take up to 1 day.

Understanding of soil systems from single particles to intact aggregates and soil cores

Mineral particles and aggregates

NanoSIMS provides elemental and or isotopic information on organo-mineral assemblages or aggregates in a spatial context from intact soil isolates. The combination of high-resolution microscopy and isotopic probing enables spatially-referenced information to be obtained on the isotopic composition of materials. Therefore, it is used to produce high-resolution 2-D maps (lateral resolution of ca. 100 nm) of the elemental/isotopic abundance in thin surface layers (penetration of the NanoSIMS primary ion beam $\sim 10\ \text{nm}$) of a soil isolate. These can either be organo-mineral associations obtained from the soil after a disintegration step, such as physical soil fractionation or from aggregates conventionally isolated from the soil by sieving. Frequently the so-called

organo-mineral associations are small micro-aggregates comprising organic and mineral particles. A major focus of such investigations has been to identify preferential associations of OM with certain mineral phases. This approach provides a visual demonstration and quantification of organic material in interaction with metal oxides and can directly prove previous indirect demonstrations by correlation. In such materials, soil minerals and organic matter can be distinguished and classified in NanoSIMS images using the distinction between OM-derived secondary ions ($^{12}\text{C}^-$, and $^{12}\text{C}^{14}\text{N}^-$) and mineral-derived secondary ions ($^{16}\text{O}^-$, $^{28}\text{Si}^-$, $^{27}\text{Al}^{16}\text{O}^-$, and $^{56}\text{Fe}^{16}\text{O}^-$). Several different mineral phases have been identified by NanoSIMS from the combined occurrence of these ions. Examples include iron and aluminum (hydr)oxides and allophane (Keiluweit et al., 2012; Patzner et al., 2020), phyllosilicates, such as smectite or illite (Steffens et al., 2017). With respect to the composition of organic matter it is to some extent possible to differentiate materials that contain only carbon based molecules, such as lipids, polysaccharides, or lignin from those that contain carbon and nitrogen based materials together, i.e., materials most probably derived from amino acids (proteins) or amino sugars (murein) (Witzgall et al., 2021). To evaluate the data obtained, suitable image analysis and statistical procedures are necessary to provide quantitative information. To facilitate interpretation of the results from NanoSIMS analyzes correlative imaging (e.g., SEM) and additional imaging data (e.g., fluorescence imaging) can be valuable.

It is possible with image analysis tools to quantify the proportion of mineral surfaces covered with organic matter and also the size and shape of the organic matter patches associated with the minerals from isolated soil organo-mineral particles (Vogel et al., 2014). At the same time information is provided on their elemental/isotopic composition. This is important and useful additional information because both the nature and strength with which OM binds to mineral surfaces are known to depend upon both the mineral type and mineral surface area.

NanoSIMS imaging may also be profitable for investigating intact three-dimensional micro-structures in soils, such as aggregates. To obtain adequately flat samples for analysis, larger soil aggregates and intact soil cores typically require embedding and subsequent cutting or thin sectioning (Mueller et al., 2017). Mineral particles pose a challenge to elemental mapping and isotope tracing experiments in intact soil matrices because they make embedding and thin-sectioning more difficult, and can cause electrical charging effects, all of which need to be considered in such analyzes (see detailed discussion in the section on sample requirements). For example, the resin embedding approach has been used to prepare a cross section of an intact soil macroaggregate for elemental in situ mapping of organic and mineral components from an arable Luvisol topsoil (Steffens et al., 2017) which is displayed in Fig. 2.

The main strength of NanoSIMS is the highly accurate isotope detection that makes it an unprecedented tool for stable isotope labeling experiments to reveal the spatial distribution and dilution of an isotopic tracer as it is incorporated into different soil compartments (e.g., microorganisms, organo-mineral associations). The co-detection of organic and mineral-derived elements enables us to study the association between these components in soils, whereas use of isotopic labels enables study of specific processes by following the label during its way into and through different soil components. It has been mostly used for tracking stable isotopes during organic matter decomposition, such as ^{13}C and ^{15}N onto distinct minerals in an intact micro-environment (e.g., Herrmann et al., 2007; Keiluweit et al., 2012; Kopittke et al., 2020; Remusat et al., 2012; Vogel et al., 2014). There are several advantages over the analysis of label(s) in bulk soil or soil fractions. One is of course that it is possible to follow the association of the labelled material directly or its transformation products specifically on mineral surfaces after isolation or within aggregates. It also provides the wide range of concentrations observed in the isolated soil fraction, and information on the processes beyond bulk data (mean values) measured with conventional isotope analysis. If both ^{13}C and ^{15}N labels are applied, NanoSIMS analyzes of specific soil fractions allow spatial differentiation of unlabeled OM (^{12}C and $^{12}\text{C}^{14}\text{N}$) and OM either double labeled (^{13}C and $^{13}\text{C}^{15}\text{N}$) or OM carrying one single label in association with minerals. Based on the NanoSIMS measurements $^{13}\text{C}^-/^{12}\text{C}^-$ and $^{12}\text{C}^{15}\text{N}^-/^{12}\text{C}^{14}\text{N}^-$ ratios can be calculated and compared to the natural abundance of an unlabeled control sample to examine how the labelled OM is incorporated and distributed in the soil material or specific soil fraction. Rumpel et al., (2015) took advantage of a field experiment with ^{13}C and ^{15}N labelled root material. They found that stabilization of root material by interaction with metal oxides occurs at different soil depths within a time frame of years. Kopittke et al. (2018) showed that N-rich microbial products preferentially attached to distinct areas of mineral surfaces compared to C-dominated moieties (Fig. 3), demonstrating the ability of soils to store additional OM in newly formed organo-mineral associations on previously OM-free mineral surfaces. They also found differences in ^{15}N enrichment between a smectite-dominated Vertisol and a kaolinite-dominated Alfisol, showing the importance of mineral composition in regulating the binding of organic compounds of most probably microbial origin in soils.

A recommended approach is also to combine the submicron characterization of isotopic label distribution by NanoSIMS with structural and chemical information from other methodologies such as TEM, scanning transmission X-ray microscopy (STXM) or near edge X-ray absorption fine structure spectroscopy (NEXAFS) (Keiluweit et al., 2012). Remusat et al. (2012) have shown how the combination of NanoSIMS, STXM and NEXAFS enabled relating the distribution of ^{15}N with the presence of microbial metabolites in intact soil aggregates, indicating the potential of this technique for in situ SOM analysis. Extracellular polymeric substances (EPS) are expected to be an important source for the formation of mineral-organic associations in soil. Liu et al. (2013) investigated the composition of EPS before and after adsorption to goethite, in combination with Raman spectroscopy and scanning transmission X-ray microscopy. They could show that organic coverage on goethite minerals was heterogeneous, consisting of $\sim 100 \times 200$ nm large patches of either lipid-rich or protein-rich material. NanoSIMS analyzes in combination with XANES of S at the K-edge provided information on the distribution and forms of As, Fe, S and OM in soils under redox level oscillations. With this approach Al-Sid-Cheikh et al. (2015) could identify ternary interactions between OM, FeO and As, which is often considered to play a major role in As-OM interactions under oxic conditions, but also a second ternary interaction between OM, S and As. Du et al. (2018) investigated the Cd sorption on ferrihydrite-OM composites formed by coprecipitation versus adsorption of OM and applied NanoSIMS in combination with Cd K-edge EXAFS. They demonstrated that the binding of Cd is a function of

Fig. 3 Two-dimensional NanoSIMS images for microaggregates derived from an Alfisol after incubation with labelled plant residues (Kopittke et al., 2018). The images demonstrate one region of interest (ROI) that is assessed by scanning electron microscopy (SEM) prior to NanoSIMS measurement. (A) In the scanning electron microscope (SEM) image microaggregates are displayed that were deposited on a silica wafer. The dashed line indicates the region of the sample that was examined after SEM analysis using NanoSIMS. (B) The $^{13}\text{C}/^{12}\text{C}$ isotopic ratios are displayed with the ^{16}O signal in grey scale as background to depict the mineral particles. The natural abundance for ^{13}C (0.011, in panel (D)) is shown on the color scale, indicating brighter colors to correspond with ^{13}C enrichment. (C) The $^{12}\text{C}^{15}\text{N}/^{12}\text{C}^{14}\text{N}$ isotopic ratios are displayed in the same way as $^{13}\text{C}/^{12}\text{C}$, with the corresponding natural abundance marked in the color scale (see also 0.0037 in panel (F)). The sum of the C and N distribution in (B) and (C) demonstrate the total area of the microaggregates that is covered with OM. Based on a number of ROIs (n in the box plots) from multiple NanoSIMS measurements, box plots of the $^{13}\text{C}/^{12}\text{C}$ and $^{12}\text{C}^{15}\text{N}/^{12}\text{C}^{14}\text{N}$ ratios can be obtained as shown in (D) and (E). Natural isotope abundance is highlighted by the red line indicates. Hot spots of ^{13}C and ^{15}N enrichment are demonstrated by 'outside values' (>1.5 times the distance between the 25th and 75th percentiles) and 'far outliers' (>3 times the distance). The figure is adapted from Figs. 2 and 3 of Kopittke PM, Hernandez-Soriano MC, Dalal RC, Finn D, Menzies NW, Hoeschen C and Mueller CW (2018) Nitrogen-rich microbial products provide new organo-mineral associations for the stabilization of soil organic matter. *Global Change Biology* 24(4): 1762–1770.

the C loading for both types of ferrihydrite-OM compounds. In a study by Vidal et al. (2019) the TEM examination of earthworm cast aggregate ultrathin sections provided visual identification of the added labelled plant residue features. The same ultrathin section used for TEM was used for NanoSIMS tracing of elemental and isotopic composition. This combined approach allowed the identification of different types of organic matter (plant residues, microbial remains) in the cast aggregates, and at the same time the freshly incorporated residues could be differentiated from the indigenous organic matter by mapping ^{13}C using NanoSIMS. This kind of combined approach, NanoSIMS image analysis joined by complementary microscopy (SEM-EDX, STXM/NEXAFS), has been used several times now and seems to be a particularly profitable way to infer the molecular and spatial fate of labeled organic materials in a mineral matrix. It has the potential to contribute further to a mechanistic understanding of sorption, occlusion, and decomposition processes that operate at fine spatial scales. As outlined above, such analyzes should be combined with classical SEM and micromorphological studies for an accurate assessment of OM distribution in the soil and its relationship to ecological processes at larger scales.

Interfaces of soils and biota

The main hot spots for biogeochemical cycles in soils are the interfaces between biota and mineral soil constituents, with plants and their residues being the most prominent biota that drive soil processes due to their large OM input. Most organic matter enters soils either from decaying above- and below-ground plant litter or the input of living roots, so called rhizodeposits. Although large volumes of soil are affected by these processes, the transformation of plant-derived OM into SOM takes place at distinct microscale

biogeochemical interfaces between plants and their residues, microorganisms and soil minerals, either in the rhizosphere (volume of soil directly affected by root activity) or the detritosphere (volume of soil affected by decaying plant residues). NanoSIMS can also provide an approach to follow directly the fate of plant-derived OM into microorganisms and soil particles at these μm scale soil interfaces. However, these process sites are within a highly complex 3-D soil matrix that complicates sample preparation for imaging approaches. Elucidation of the physical structure of intact rhizosphere or detritosphere soil volumes is relatively easy using X-ray micro computed tomography (CT) (Schlueter et al., 2019), whereas the preparation of meaningful intact flat samples for electron microscopy or NanoSIMS requires specific sample treatments described above. The preparation of embedded cross sections ensures the integrity of the 3-D structural arrangement of the biota-soil interface for meaningful micrometer analyzes. The preservation of biological cell morphologies and spatial arrangement of analytes is mostly done by chemical fixation (Herrmann et al., 2007; Mueller et al., 2013). One classical procedure for sample preparation is to preserve the sensitive plant and microbial cell structures using chemical fixation followed by dehydration with a series of water to solvent mixtures and final embedding in a polyester or epoxy resin. The embedded sample can then be sectioned and polished if a flat sample surface with low topography is needed. This approach gave good results with NanoSIMS for studying intact rhizosphere and detritosphere samples. Other imaging techniques are also possible in combination with NanoSIMS, for example fluorescence microscopy to localize microbial cells (Schlueter et al., 2019; Vidal et al., 2018). For very sensitive samples and the need to preserve highly mobile elements e.g., potassium, it is also possible to use flash freezing and cryo-substitution (Kilburn and Clode, 2014). If the sample itself is vacuum stable and has large flat areas with low topography it can be examined directly without embedding. Fine structures like thin roots and fungal hyphae might also be analyzed directly in the NanoSIMS, and also more complex systems. For example, Witzgall et al. (2021) studied the microbial transformation of particulate OM in the detritosphere directly at the interface of ^{13}C enriched plant residues, microorganisms, and soil minerals without any embedding. If the sample surface is irregular in terms of topography there are concerns about artifacts due to differences in the ion yield of different secondary ions, but this effect is relatively small for isotopologues (e.g., $^{13}\text{C}_2$, $^{12}\text{C}_2$), the most often used molecular cluster secondary ions to trace isotopic enrichment.

As described above for mineral-associated OM, the capability of NanoSIMS to image ^{13}C and ^{15}N allows plant-derived OM at distinct plant-soil interface systems to be followed directly from the plant into microorganisms and soil particles (Gorka et al., 2019). Bulk analysis can only yield the overall enrichment for instance of a whole root, extracted microbial biomass or a sum of picked fungal hyphae, whereas NanoSIMS enables quantification of the plant-derived ^{13}C and or ^{15}N enrichment to the single cell level and to follow its transformation directly into microbial C and N as well as the buildup of SOM. This offers the opportunity to study gradients starting at the plant root, into microorganisms at the rhizoplane and mineral surfaces at certain distances from the root (Fig. 4). A fundamental property of the rhizosphere and detritosphere, the emergent development of gradients of elements and processes, can also be studied.

By separating single soil constituents (e.g., bacteria, fungal hyphae) it is possible to analyze them separately, and for example bacterial cells on fungal hyphae can be imaged (Gorka et al., 2019). However, intact biota-soil interfaces comprise tremendously complex systems for microspatial analyzes as they combine soft plant, animal or microbial cell structures and rigid soil mineral particles. In a first attempt to study the interaction and competition between plants and soil microorganisms for nitrogen in the rhizosphere, Clode et al. (2009) used a microcosm setup in which the authors grew wheat exposed to $^{15}\text{NH}_4^+$ in a loamy soil. Intact rhizosphere samples were chemically fixed, resin embedded and finally polished cross sections were produced. These samples were analyzed by transmission electron microscopy and subsequently NanoSIMS, which allowed the authors to demonstrate that microbial cells in the direct vicinity of the plant root took up most of the added ammonia. Thus, this work demonstrated for the first time the great advantage of the high spatial resolution of isotopic imaging for soil science as there is no other way to differentiate microscale elemental cycling in rhizosphere constituents (roots, bacteria, fungi, etc.) down to the single cell level. Herrmann et al. (2007) demonstrated this setup for larger soil cores and opened the way to analyze biogeochemical interfaces in more complex natural soils.

The rhizosphere, in particular, with its intricate connection between plant roots, soil microorganisms and soil minerals is at the focal point of applying NanoSIMS to follow the fate of plant-derived OM into soil microorganisms. In controlled mesocosm setups it is possible to follow the fate of photosynthetically fixed $^{13}\text{CO}_2$ from the plant root into the rhizosphere (Gorka et al., 2019). Kaiser et al. (2015) demonstrated with NanoSIMS the imaging of root cells, fungal hyphae and soil microorganisms that photosynthetically fixed OC is rapidly transferred into the roots and from there, independently from passive exudation, into arbuscular mycorrhizal and via their fungal hyphae into soil microorganisms. These authors showed that the mycorrhizal network is important for the allocation of plant-derived OC into soil microorganisms. With a split pot design in which plant roots were separated from extraradical fungal hypha, Gorka et al. (2019) demonstrated the use of two isotopic tracers, $^{13}\text{CO}_2$ for the plant-derived C and ^{15}N for litter-derived N. By NanoSIMS imaging of the $^{13}\text{C}/^{12}\text{C}$ distribution, the authors showed the uptake of hyphae-derived OC by bacterial cells residing on the hyphae itself. But this approach can also be used for samples derived from field trials. Vidal et al. (2018) used in-growth cores to sample the intact rhizosphere soil of wheat from an in situ labeling experiment, and used NanoSIMS to trace plant-derived OC into roots, rhizosphere microorganisms and soil particles. This study highlights the applicability of the methodology and analytical approach to support field experimental data by mechanistic underpinnings at the relevant process scale. In addition to the interfaces of plants and soil, those of soil biota and soil can also be assessed using NanoSIMS. Embedded cross sections of earthworm casts were used to follow the different fate of ^{13}C labelled above- and below-ground plant residues into mineral-associated organic matter using a cascade of TEM and NanoSIMS analyzes (Vidal et al., 2019). The high resolution of TEM combined with the isotopic imaging capability of NanoSIMS enabled demonstration of the intricate connection of soil microorganisms and the formation of mineral-associated OM regulated by earthworms.

Fig. 4 Images based on NanoSIMS measurements of an epoxy resin embedded cross-section of a root-soil interface of a primary root of a 21-days old maize (*Zea mays* L.) plant grown in loam labelled by both $^{13}\text{CO}_2$ and $^{15}\text{NH}_4$ enrichment. Panel (a) displays a composite image to illustrate the intricate connection of the root with the surrounding minerals, depicting plant and microbial OM based on the distribution of $^{12}\text{C}^{14}\text{N}$ (green), and mineral soil constituents based on the distribution of $^{27}\text{Al}^{16}\text{O}$ (blue) and $^{56}\text{Fe}^{16}\text{O}$ (red). Panel (b) shows the distribution of the ^{13}C ratio, and panel (c) shows the distribution of the ^{15}N ratio. The intense high color areas highlight microscale spots enriched in root derived ^{13}C and fertilizer derived ^{15}N at the surface of a soil aggregate in the vicinity of the highly enriched root (E. Lippold, C. Hoeschen, C.W. Mueller unpublished data).

Detection of microbiota in the soil environment

Soil microbiology is a vibrant field within soil science with the application of microscopic techniques. In microbiology light microscopy and fluorescence staining are used routinely, and provide an excellent basis to build on with spectromicroscopic techniques such as NanoSIMS. Sample preparation protocols that aim to preserve very sensitive biological structures like bacterial cells are important for developing imaging cascades from light microscopy to electron microscopy and NanoSIMS. The high spatial resolution and the possibility of using isotopic tracers make NanoSIMS the perfect tool to analyze individual microbial cells. This allows us to differentiate the activity and functional importance of distinct microbial phyla and/or consortia. In environmental microbiology the application of NanoSIMS for aquatic systems is relatively straightforward by analyzing cells directly fixed on filter discs. However, the study of soil microbiota at the microscale in natural soils is hampered by their sparse distribution; most microbiota accumulate at hot spots like the rhizosphere and it is difficult to assess a sufficient number of cells against a large soil background. Either the microscale analyzes focus on the functioning of such hot spots with a sufficient presence of microbiota as discussed above for the rhizosphere and detritosphere, or other methods have to be used. A relatively simple approach to yield sufficient soil microbiota from the rhizosphere together with soil particles is by shaking root samples with adhering soil in deionized water and desiccation of the suspension on a silica wafer. Although this approach does not ensure the preservation of intact microbial cells because a fixation step is missing, it can provide insight into the isotopic enrichment of fungal and bacterial cells derived from a certain soil sample. If the shaking is done in 50% ethanol cell structure preservation will be better and ensured, and thus allow the analysis of intact microbial cells (Hestrin et al., 2021). A more comprehensive method to separate soil microorganisms from the soil and increase the number of analyzable cells was developed by Eichorst et al. (2015). After chemical fixation of the soil samples, microbial cells were extracted from the soil slurries by filtering. This approach leads to a high cell density and reduced numbers of soil particles on the filters. This approach can be used to analyze more individual cells while also allowing the combination of NanoSIMS with previous staining of the cells to obtain phylogenetic information by fluorescence in situ hybridization (FISH).

An approach independent from the single cell level was developed to be able to analyze isotopic enrichment in a larger number of different phyla (Pett-Ridge and Weber, 2021). The so called NanoSIP is based on a high-density microarray approach that measures isotopic enrichments (^{13}C , ^{15}N , ^{18}O) of taxon-specific 16S (or 18S) rRNA genes by NanoSIMS. The combination allows the taxon-specific quantification of the incorporation of substrates in complex microbial communities. This is a nice example of how the high spatial resolution and high sensitivity of the NanoSIMS can be used for analyzes with higher throughput of sample numbers that cannot be measured by classical isotopic ratio mass spectrometry.

Conclusion

The conceptual understanding of the functioning of soil systems ranging from ecosystems down to microscales has developed rapidly. We have now started to understand microscale processes better with the development and increasing access to imaging techniques capable of resolving very fine soil structures down to soil aggregates, single minerals and microbial cells. With NanoSIMS the soil science community has an unprecedented tool at hand to analyze directly the elemental composition of soil interfaces and to follow the fate of elements in complex soil systems using enrichment with stable isotopes. NanoSIMS provides the important step from a single data point of, for example, a $^{13}\text{C}/^{12}\text{C}$ ratio to the detailed analysis of microbial utilization of plant-derived organic carbon at a single cell level. NanoSIMS is a strong supporting technique to underpin conceptual ideas by direct imaging of the relevant process scale and the processes and players involved. It is up to the soil science community to integrate this tool wisely into experiments and to use the large analytical tool box in conjunction to unravel soil processes at the microscale. The future might bring more research that goes beyond the use of the classical stable isotopes ^{13}C and ^{15}N , but aims at using the full mass range that can be resolved by NanoSIMS.

Abstract

Nanoparticles exist widely in soil. They could be generated by natural processes, or could be made artificially and released into the environment. Both natural and engineered nanoparticles are active components, and greatly affect the chemical processes in the soil system. This chapter describes nanoparticles in soil taking account of the following aspects: separation and identification of nanoparticles in soil, the fate and interactions of nanoparticles in soil, and the effects of nanoparticles on soil systems. The research progress and demands are discussed regarding the characterization, environmental behavior, and toxicity assessment of nanoparticles in soil.

Key points

- Both natural and engineered nanoparticles are reactive components in soil.
- They can be separated and quantified using sophisticated techniques.
- Nanoparticles are aged in soil with continuous changes in their properties.
- The negative and positive impacts should be balanced for their application.

Introduction

The word nano is from the Greek “Nanos” meaning dwarf. It is a prefix used to describe one billionth (10^{-9}). A nanometer (nm) is a billionth of a meter, or a millionth of a millimeter. Nanoparticles (NPs) usually have sizes in the range of 1–100 nm for at least one dimension. They may be formed through natural processes (NNPs) or well-controlled engineered processes (ENPs) (Pan and Xing, 2010). Unlike traditional materials, NPs show many special physical and chemical properties, such as quantum size, surface, and quantum tunneling effects. They are widely used in magnetic, microelectronic and catalytic materials, fuel cells, and biosensors.

Although nanotechnology has a promising potential in many fields, some researchers indicated the potential of biological and environmental safety issues of nanomaterials and nanotechnology several decades ago (Colvin, 2003). Because of the nanoscale effect, NPs have been proved to have strong toxicological impacts. Thus, many researchers believe that ENPs should be applied with

great care, and should be prohibited for in situ soil remediation (Tratnyek and Johnson, 2006). However, nanomaterials may be released into the environment through different pathways. The identification and differentiation of NNPs and ENPs are therefore important for studies on NPs and their environmental risks.

Natural and engineered nanoparticles in soil

Naturally occurring nanoparticles

Natural occurring nanoparticles (NPs) occur widely in soils, sediments, volcanic dust and ash, ocean surface microlayers, and other natural waters. Soil is a reservoir of inorganic and organic NNPs such as clay minerals, humic substances, and metal oxides. The NNPs in soil are mainly the combined result of long-term physical, chemical and biological processes. For example, they could be the products of minerals weathering or microbial activities. Chemical weathering tends to produce metal oxide NNPs like magnetite and hematite. The NNPs produced by biological processes also include humic NPs as well as iron and manganese oxides.

The NNPs in soil are mainly nano-clay minerals, which are generally composed of nano-layered silicate, amorphous nano-silicate, and metal oxides such as iron and aluminum oxides. Their large surface areas make their surfaces ideal for immobilizing enzymes, retaining harmful substances, and adsorbing nutrients needed by plants. For example, natural nano-ball allophane is a hollow spherical amorphous silicate with a diameter of 3.5–5.0 nm and a surface area of 700–900 m² g⁻¹. The loaded enzymes have greater mobility and activity on the nano-ball allophane because of the hollow sphere structure. Thus, the interface reaction activity of soil particles is enhanced by the allophane nanoclay. In soil, the particle size of natural iron and aluminum oxide ranges from 5 to 100 nm. For instance, hematite (α -Fe₂O₃) NPs can quickly adsorb heavy metal ions such as Cu²⁺, and can also catalyze Mn²⁺ to manganese oxide minerals. It should be noted that NNPs in soil usually exist in the form of organic-inorganic complexes, namely organic coatings on mineral particles. For allophane, the coated organic matter may significantly increase the adsorption of heavy metals. The organic-inorganic complexes may also facilitate the electron transfer between NNPs and microorganisms or pollutants. However, the active sites could be blocked after organic matter coating, which can consequently decrease the reactivity of NNPs.

Thus, NNPs are important constituents of soils because they are involved in numerous fundamental biogeochemical processes, such as water regulation, elemental cycling and bioavailability through the sorption, retention and transport of nutrients, natural organic matter and organic-inorganic contaminants (Nowack and Bucheli, 2007). These processes are strongly influenced by the physicochemical properties of NNPs as well as their interaction with soil components.

The origin of engineered nanoparticles in soil

In the past two decades, nanotechnology has attracted great attention and has been widely used in various fields. Engineered nanoparticles (ENPs) are NPs designed and produced for a specific purpose, also with a size of 1–100 nm at least for one dimension. The ENPs can be divided simply into two categories according to whether they contain carbon or not: carbon-based material NPs and inorganic engineered NPs, respectively. The most common carbon-based material NPs are fullerenes and carbon nanotubes. They have a large specific surface area, electron transfer properties and thermal properties, and so they have been widely used in the fields of medical sciences, pollutant adsorption and degradation. The inorganic engineered nanomaterials include nano-metal, nano-metal oxides and metal salts. Silver (Ag) NPs have highly effective antibacterial properties which can inhibit a variety of bacteria, fungi and viruses, and thus are used as supplements in antibacterial fibers, fabrics, plastics, ceramics, and antibacterial coatings. Nano-Ag antibacterial products are also favored by the majority of consumers. However, with their strongly antibacterial properties, the release of Ag NPs into the environment inevitably increases concerns about the risks to the ecosystem. For example, Ag NPs may be released from commercially available Ag-containing socks during washing. In the water after washing socks, 3.0–1300 and 1.5–650 µg Ag were detected in both granular and ionic forms, respectively. Similar releases of Ag NPs can be expected for toothbrushes, clothes, and cooking wares (Nowack and Bucheli, 2007). These ENPs may be released through washing, sweating or rainwater scouring, and then enter the urban sewage network. Conventional municipal sewage treatment does not deal with NPs, and consequently they enter into the environment after wastewater treatment.

With the development of nano science and technology, more and more nanomaterials are applied to our daily life. “The Nanodatabase” (Danish Consumer Council) lists a total of 5040 ENPs-containing products for 2020, four times more than for 2012 (the first report). These ENPs are widely used in textiles, cosmetics, daily necessities, household appliances, medical, electronics, coatings, catalysts, sensors, semiconductor materials and machinery manufacturing. It is easy to envisage that during the synthesis of ENPs, the manufacturing, utilization, abrasion and disposal of nanoproducts, ENPs will be constantly released into the environment. Some of them enter the urban sewage treatment system, and may end up in sewage sludge and wastewater treatment facilities after water treatment processes. Even the land application of treated sludge and treated wastewater may introduce ENPs to the environment. A small portion of ENPs may enter the soil and water environments directly through atmospheric deposition, wet deposition, and surface runoff, and finally accumulate in the sediments and soil. With their small size and special morphology, ENPs often have unique physical and chemical properties. It should be noted that these anthropogenic particles may induce ecological toxicity, or become carriers of other pollutants, posing potential environmental risks.

Identification of nanoparticles in soil

Separation of nanoparticles from other particles

Separation or extraction of NPs is a prerequisite for studying the fate of NPs and the implications. However, the separation of NPs from the soil matrix is extremely challenging because of their small particle size and easy aggregation. The aggregation of NPs may occur among the same NPs (homo-aggregation) or among different NPs or even NPs and other substances (hetero-aggregation). In soil systems, NPs tend to associate with organic matter and other particles forming hetero-aggregates, especially in the presence of multivalent cations. Extraction of NPs from soils usually comprises a combination of different processes, such as sonication or dispersion of the particles in a liquid followed by size separation through centrifugation or filtration.

Ultrasonication is an effective method to disperse NPs from soil and has been widely used. When the ultrasonic wave is applied in the suspension, a large number of small bubbles will be produced in the liquid due to escape of the supersaturated gas. As the bubbles grow and burst continuously, they disperse the particles in the suspension. To ensure the effectiveness of the dispersion, ultrasonic temperature, energy, and time are adjusted depending on the concentration of the suspension, soil type, organic matter and even mineral compositions.
